AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences.

District Conferences will be held as follows:—

Hills, at Coromandel Valley (Blackwood Branch), Thursday, August 23rd, H. Goldsack, Coromandel Valley (Secretary).

Eyre's Peninsula (Southern), at Yeelanna, Wednesday, September 5th, R. R. Wilson (Secretary).

Eyre's Peninsula (Central), at Kyancutta, Friday, September 7th, E. A. Kelly (Secretary).

Pinnaroo Line, at Pinnaroo (Parilla Well Branch), Tuesday, September 18th, E. C. Slater, Pinnaroo (Secretary).

Murray Lands (East), at Caliph, Thursday, September 20th, W. H. Todd (Secretary).

Fruit (Non-irrigated Districts), at Balhannah, Tuesday, November 6th, C. G. Grasby (Secretary).

In each case the Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda.

Agricultural Shows.

We have been advised by Secretaries of Agricultural Show Societies that their shows will be held as follows:—

Maitland, Wednesday, September 26th.
Denial Bay, Friday, September 28th.
Gawler, Saturday, September 22nd.
Balaklava and Dalkey, Saturday, September 29th.
Jamestown, Wednesday, October 10th.
Karoonda, Wednesday, October 3rd.
Loxton, Wednesday, October 10th.
Burra, Wednesday, October 24th.
Minlaton, Wednesday, October 24th.
Mount Gambier, Wednesday and Thursday, October 24th and 25th.
Murray Bridge, Thursday, October 25th.
Woodside, Saturday, November 3rd.

Registration of Stallions.

Under the Draught Stallions Acts, 1932-33, it is compulsory for owners to register all draught stallions of two years and over. The list of stallions registered to June 30th, 1934, is published in the *Government Gazette* of August 16th, and reference is made to those stallions which have so far been examined and have secured certificates. The Chief Inspector of Stock (Mr. C. A. Loxton) points out that some owners are of the opinion that it is not necessary to register stallions which are not used for hire. This opinion is wrong, as all draught stallions, whether used for hire or exclusively on owners' farms, must be registered in accordance with the Act.

Congress.

...proval has been given to hold the Annual Congress this year on the same conditions ...ve applied in the past. The opening session will be on Monday, October ...delegates and other members of the Agricultural Bureau are requested to ...e at 7.45 p.m. The congress will be continued on October 9th and ... evening sessions.

Financial Relief Act (Federal).

Information has been received from the Prime Minister that the Financial Relief Act of 1934 provides for the granting of assistance to primary producers, other than wheat growers, by making a payment to them out of Commonwealth funds at the rate of 15s. per ton for each ton of artificial manure used by them. The period during which the fertilizer is to be applied to the soil is July 1st, 1934, to June 30th, 1935. The terms and conditions are generally the same as those of the Act which was passed in 1932, and provided for a similar grant. Provision is also made for assistance to growers of apples and pears to an extent equal to that which was made available last year, the methods and terms of distribution being left entirely to the States. The allocation among the States has been based on the same principle as last year, viz., the exports during the financial year immediately preceding that in which the grant is to be made.

Wheat and Mill Products—Why Prices Vary in Different States.

At the Conference of Upper North Branches of the Agricultural Bureau, held at Wilmington on July 18th, a delegate from the Morchard Branch asked "What is the explanation of the higher price for wheat in Melbourne and Sydney over Adelaide prices, and the lower prices for flour, bran, and pollard in those cities?" The following reply was supplied by the Secretary of the Co-operative Wheat Pools Limited:—"Farmers and others who study interstate produce market reports are likely to be puzzled at the marked difference in prices of wheat and mill products in the several capital cities, and the apparent inconsistencies that exist in some instances. These differences may be accounted for in several ways, but as they are not apparent in the published reports, most readers will probably gain wrong impressions therefrom.

The press reports of wheat, flour, and offal prices at the end of June were as follows:—

	Wheat (Bushels) Shipper's Price for farmers' lots.		Flour (Ton).			Bran (Ton).			Pollard (Ton).		
	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.
Adelaide	2	6½	7	17	6	5	5	0	5	0	0
Melbourne	2	8½	7	12	6	4	5	0	4	15	0
Sydney	2	9	8	0	0	4	5	0	5	0	0
Perth	2	8	8	5	0	4	17	6	5	7	6

As regards wheat quotations it must be remembered that they are subject to deduction for receiving agents' commission, which amounts to 1½d. per bushel in South Australia, also freight charges from receiving point to shipping port, so that the farmer actually receives substantially less for his wheat when delivered at a country siding than the price quoted in the press. On the other hand quotations for millers' parcels are usually several pence a bushel higher than those for farmers' lots, the difference representing the merchants' handling costs and profit.

Apart from the consideration that the rate of commission paid agents varies as between the different States, there are several other factors which tend to place South Australian prices below those quoted in other parts of the Commonwealth. One of the chief depressing influences is the high shipping charges imposed on wheat in South Australia; first, there is wharfage, which absorbs nearly one halfpenny a bushel. This is a charge which is not levied on shipments from Victoria or Western Australia, and is much higher than the rate in New South Wales. Port dues and other items make the total charges in South Australia by far the highest in the Commonwealth, and as under the present system of trading prices are based on the inequitable "London parity" basis all these charges ultimately are borne by wheatgrower.

he matter of shipping freights, too, South Australia is at a disadvantage on f her geographical position. Western Australian shippers receive an freight both to Europe and the Orient, and this may amount to as

much as one penny per bushel. Victoria and New South Wales also enjoy some advantage in freight to eastern ports. The concentration of shipping to one or two ports is another advantage enjoyed by the eastern States, one tangible result being the greater amount of parcel freight for both wheat and flour available for shipment from Melbourne and Sydney, and parcel freight rates are usually substantially lower than full cargo rates. Parcel space from South Australian ports is decidedly limited, and is rarely available for any other port than Adelaide, which is especially disadvantageous as regards wheat shipment.

A distinct advantage has been won for Western Australian wheat in that its quality has for some years been uniformly superior to that grown in other parts of the Commonwealth. Overseas buyers have appreciated this fact, and a premium of from 1d. to 2d. per bushel is frequently obtainable for western wheat.

The fact that wheat may be purchased in bulk in New South Wales and Western Australia also has an influence on the price as buyers under that system are assured of a more uniform and cleaner sample.

The larger demand by millers in New South Wales and Victoria is probably the principal influence which keeps wheat prices there above those in South Australia. Both the eastern States have considerable trade in export flour, in addition to a much more extensive local trade than is available in this State. The extent of the export flour position may be realized from the figures relative to the 1923-33 season. In that year New South Wales exported 234,000 tons, Victoria 221,000 tons, and South Australia 56,000 tons. The local trade both in New South Wales and Victoria is at least three times as great as in South Australia.

As regards flour it will be observed that while the Adelaide price is above Melbourne it is below the Sydney and Perth figures. It has been explained that there are certain differences in the basis of quotation in the various States. For example, South Australian prices cover delivery to buyers' premises, including many country towns, while in Victoria there is a scale of charges for delivery. These differences may account, in part at least, for the disparity in prices, but the greater turnover previously referred to is, no doubt, a very important factor in the milling industry, and it has enabled the milling concerns in the eastern States to install the most modern and economical equipment and reduce the ratio of overhead charges to a minimum.

The position with regard to mill offal is similar to that which applies to flour. There is a difference in the basis of quotation—Adelaide prices being subject to certain discounts for delivery ex mills and for truck load quantities, while eastern States prices are nett for truck loads. There is a wider demand for offals for stock feed purposes in the eastern States, and the greater turnover again would allow lower production costs and distributing charges.

Crop Competitions.

The Government has approved of a grant of £100 for distribution among the various District Crop Competition Committees for this year. Intending competitors are reminded that they should communicate with their District Secretary intimating their intention to compete.

District Secretaries are as follows:—

District. Secretary. Address.

Albert—G. H. Sutherland, Copeville.
Alfred—G. L. Chinner, Box 68, Loxton.
Balaklava—J. D. Harkness, Owen.
Buxton—F. R. Illman, Box 64, Kimba.
Central—E. Day, Wasleys.
Chandos—H. G. Johnston, Parilla.
Far Northern—E. J. Martin, Orroroo.
Flinders—R. R. Wilson, Yeelanna.
Hopetoun—H. V. Hobbs, Coorabie.
Jervois—F. Coles, Mangalo.
Le Hunte—F. L. Johnson, Wudinna.
Midland—F. W. Coleman, Saddleworth.
Mid-Northern—W. Pengilly, Yacka.
Mid-Yorke Peninsula—E. H. R. Dutschke, Box 2, South Kilkerran.
Northern—J. E. Lehman, Caltowie.
Northern Yorke Peninsula—S. G. Chynoweth, Boors Plains, Kadina.
Robinson and Dufferin—H. Doley, Box 8, Wirrulla.
Russell and Buccleuch—G. R. Tregilgas, Yurgo.
Southern—J. M. Hudd, Bletchley.
Southern Yorke's Peninsula—H. W. Cornish, Stansbury.
Tatiara—W. Flower, Bordertown.
Upper North—W. J. Ninnes, Tarcowie.
Way—G. W. Denton, Charra.
Western—A. M. Lawrie, Nelshaby.

Herd Testing Fees.

For the financial year 1934-35, the herd entrance fee for official herd testing will be reduced from £6 10s. to £3 5s., and the 10 per cent. levy on the selling price of bulls will be waived. The waiving of the levy will be made possible by an anticipated saving in having the official testers present at two consecutive milkings instead of three.

In consequence of the reduction in the herd entrance fee by £3 5s., the minimum cost per herd for official testing will this year be £5 5s. instead of £8 10s. This sum will cover the testing of four cows.

Where the fees for 1934-35 have been paid in excess of what is now required under the new scale of charges refunds will be made. If, on the other hand, fees are still outstanding, payments should be made early.

Under the new arrangement whereby official testers will not stay so long at each dairy, it will be possible for them to visit a larger number of breeders, and consequently it is expected that there will be vacancies for several more herds.

Deputy Chief Horticultural Instructor.

Mr. A. G. Strickland, who was recently appointed Deputy Chief Horticultural Instructor, holds the degrees of Bachelor of Agricultural Science and Master of Agricultural Science in the University of Melbourne. He joined the Horticultural Division of the Victorian Department of Agriculture, where he held the position of Horticultural Research Officer at the time of his appointment to the South Australian Department. In the Victorian Department his duties were largely of an investigational nature and included general routine and extension work in various branches of horticulture. He thus became associated with experimental and observational work on a wide range of horticultural crops and problems, as indicated in the following summary:—Research on deciduous fruits in regard to manuring, stocks, pollination, removal of spray residues, and fundamental statistical work in the planning and technique of field trials with horticultural crops; the determination of a proper basis for field experiments with grape vines and the initiation of carefully planned fertilizer experiments on wine grapes at the Rutherglen Viticultural Station; the conduct of experiments in regard to the cultural and disease problems of tomatoes, and the charge of the departmental experimental field at Bendigo; association with field and laboratory work in connection with the soil alkali and drainage investigations conducted by the Irrigation Research Committee at Tresco; extensive experience in irrigation practice and soil and drainage problems at Tresco; inquiring, as a member of a committee, into the loss of large numbers of canning-fruit trees in the Goulburn Valley Irrigation Area in 1931; experiments in regard to fruit storage, and investigations carried out by the Citrus Preservation Committee; responsibility for directing and examining the results of fundamental experiments dealing with the effects of orchard variation on sampling methods in storage experiments.

Mr. Strickland travelled extensively throughout the fruit-growing districts of Victoria, and gained a wide experience in the preparation and delivery of lectures at meetings of orchardists. He has written articles on "Spray Residues on Fruit—Methods of Removal," "Harvesting Apples," "Winter Injury to Peach Trees," "A Wine Uniformity Trial," "Tomato Culture—Raising Healthy Seedlings," "The Pollination of Fruit Trees," "Removal of Arsenical Spray Residues from Apples," "Tomato Investigations at Bendigo, 1929-30," "Strawberry Culture," and "Orchard Manuring."

AGRICULTURAL INQUIRIES.

[Replies supplied by Mr. W. J. Spafford, Deputy Director of Agriculture.]

Manurial Value of Bone Manure and Sheep Droppings.

Waikerie asks—What are the analyses of No. 1 Bone Manure and Sheep Droppings, and what are their comparative values as fertilizer?

Reply (supplied by Mr. W. J. Spafford, Deputy Director of Agriculture)—It is impossible to make a proper comparison between No. 1 Bone Manure and Sheep Droppings, because the former supplies nitrogen and phosphoric acid, but no organic matter, whereas the latter is essentially an organic manure containing a little plant food. The analyses of the fertilizers are as follows:—

Fertilizer.	Nitrogen. (N)	Potash. (K_2O)	Phosphoric Acid. (P_2O_5)
	%	%	%
No. 1 Bone Manure	7·50	–	11·45
Sheep Droppings—			
Dry (15% water)	1·99	1·61	0·55
Fresh (64·6% water)	0·83	0·67	0·23

No. 1 Bone Manure is £9 10s. per ton, and if the phosphoric acid in it costs 3s. 10d. per unit (per cent. per ton), which it does when acid-soluble phosphate is 1s. 9d. per unit, as at present, then the nitrogen will be worth 19s. 6d. per unit. Using these figures of 3s. 10d. per unit for phosphoric acid, 19s. 6d. per unit for nitrogen, and 7s. per unit for nitrogen and 7s. per unit for potash (as in muriate of potash), the manurial constituents of Dry Sheep droppings are worth £2 12s. 2d. per ton, and in Fresh Sheep Droppings, £1 1s. 9d. per ton.

It must not be lost sight of, however, that the chief value of animal droppings does not depend upon the manurial constituents contained in them, but their greatest worth is as a soil improver. The Soil Amendment value of organic manure is very difficult to state in terms of pounds, shillings and pence, but it is very high for the fruit-growing districts of the Murray River.

(Southern Conference, Strathalbyn, August 16th, 1934.)

Meadow Hay.

Port Elliot: "What is the best method of making meadow hay?"

Reply: The method employed in the making of meadow hay in the Adelaide Hills varies according to the weather experienced at the time of cutting the forage and according to whether clover or grass predominates in the pasture.

If there is more Subterranean clover than grass present, the material should be cut as soon as the clover shows signs of maturing, which is evidenced by some of the base leaves beginning to become yellow, and the presence of plenty of seed burrs at the surface of the ground. If, however, grass predominates, whether it be Rye grass, Soft Brome, Great Brome, or Silver grass, the hay should be cut soon after the grass has headed.

When the weather is fine at haymaking time, the mowers should not be started until after the dew has dried from the crop, because external moisture is harmful to meadow hay, and if fairly plentiful may ruin the forage. This is so important that it is usual with many successful makers of meadow hay to delay cutting for some days if the weather is dull and damp.

Should it be necessary to cut the forage when wet, it is left in the swath until the surface dries before being raked into windrows; but when the weather is favourable for haymaking the material can be put into windrows as soon as cut, and after being left there for about half a day is built into cocks. If the weather is dry during haymaking, the cut forage is put into cocks as soon as possible after cutting. To hasten curing and to facilitate handling, the cocks should be of such size that they can be lifted at a single forkfull.

Meadow hay should not be left out in the field longer than is necessary to cure it, but should be stacked or baled as soon as ready, and a common test to help decide when to stack is to take a handful of the hay from the centre of a cock and twist it very tightly, and although it may feel moist to the hands, if no sap is squeezed from the stalks it is quiet safe to cart to shed, stack, or press. If stacked when too moist there is a danger of decomposition and the development of moulds, and in extreme cases the heat developed may lead to spontaneous combustion, and when there is the least fear that the hay being stacked is too moist a liberal supply of salt should be added to each layer of hay to keep down the decomposition.

Meadow hay is so valuable that it should be stored in sheds instead of in exposed stacks, wherever it is possible to do so, and if large quantities are to be cured and stored it is probably better to press it into bales in the field and store the bales of hay in a shed.

Low Quality Wheats in South Australia.

Hartley: *Are there too many low quality wheats grown in South Australia?*

Reply: Because of the fact that in days gone by wheat merchants have made weight per bushel the only standard of quality, farmers have sought heavy-yielding varieties of wheat which also weighed well, and breadmaking qualities have been sadly neglected.

DUNLOP
"Only in Dunlop do you get the EXTRA Safety of a road-grip right across the tread!"
DUNLOP
Gold Seal
The greatest tyre in British History.

The result has been that our flour has deteriorated and exported wheat is not purchased as readily as was the case at one time. Fortunately the position is not so very bad in South Australia that it cannot be rectified fairly quickly, and now that all wheat-breeders, most local millers, and many up-to-date wheatgrowers are alive to the need of improving the breadmaking qualities of the wheats grown in the country an improvement can be expected in the near future.

Most of the varieties of wheat commonly grown in the State possess fair quality, but there are a few fairly prominent ones much below standard, and probably the worst one in this direction is Gallipoli, because it is such a heavy-yielding variety in all sorts of conditions, but unfortunately the flour produced from it is of very low quality.

If a variety can be found that will behave as well in the field as does Gallipoli, and at the same time produce grain of good quality, we would again be able to sell our wheat fairly readily; but more than this must be done, for if we are to hold the overseas wheat markets against other countries with similar climate we must develop new wheats which will give heavy yields of grain of a quality above that of most of the well-known varieties now grown. Roseworthy Agricultural College has already started work in this direction, and with the aid of the Pelshenke test for quality, is hopeful of producing new varieties capable of increasing the yield of the State and at the same time improving the quality of the flour produced from our wheat.

Most Suitable Breed of Ram to Produce Fat Lambs.

Port Elliot: What is the best breed of ram for fat lambs?

Reply: For the production of fat lambs in South Australia the Southdown is the most useful breed to use as the sire of the lambs. This is largely due to the facts that:—

1. The great bulk of our fat lambs are exported to Great Britain, where the highest-priced lambs are of short carcass, broad of back, deep in the hind quarters, carrying the minimum of bone, and sired by a black-faced ram, and the Southdown ram is the one which produces this type with more certainty than does any other breed.

2. The Southdown retains its high rate of fertility in our warm climate a good deal better than most other of the mutton-producing breeds of sheep, with the result that more lambs are secured from a given number of ewes when mated to Southdown rams.

3. Most of the ewes used as dams of fat lambs in this country are of the Merino breed, and because of the small size of the Southdown very little trouble is experienced at lambing time and loss of ewes is exceptional when Southdowns are mated to ewes of any breed.

4. Although lambs sired by Southdown rams do not develop so rapidly as lambs by some other breeds of rams, they possess wonderful fattening qualities, and practically all lambs bred by Southdown rams eventually become marketable, no matter how severe the conditions were whilst being reared. This power of recovering from a setback received when young is of great value in those districts where feed might be short at lambing time.

5. Lambs by Southdown rams lose less on slaughter than lambs by any other breed of ram.

6. When fat lambs are reared under ordinary farming conditions in South Australia, those by Southdown rams will produce a higher percentage of first-grade lambs than will any other cross.

Under some special circumstances other breeds of rams may prove more suitable than the Southdown for producing fat lambs, but for South Australian conditions generally no other breed has been proved to equal the Southdown.

ERGOT POISONING.

Reporting that sickness in horses in the Petina district had been diagnosed as "ergotism," the Secretary of the local Branch of the Agricultural Bureau has been advised by Mr. R. H. F. Macindoe, B.V.Sc., M.R.C.V.S., Deputy Chief Inspector of Stock, that ergotism or ergot poisoning is due to the eating of rye, various kinds of hay, or grasses infested with the ergot fungus (*Claviceps purpurea*). It is a rare disease in this State, the characteristic feature of ergot poisoning being an irritation and pain of the extremities of the body, such as the feet and tail. Later, areas of the skin become gangrenous and may slough off. There are two forms recognised:—(*a*) Animals become dull and listless, cold sweats break out on the neck and flanks, breathing slow and deep, temperature below normal, pulse weak, and death occurs during deep coma (unconsciousness). In other cases, where the amount of contaminated fodder taken has been small and over a longer period of time, there may be diarrhoea, colic, and symptoms of severe abdominal pain. (*b*) The gangrenous form. *Treatment.*—Where it is definitely known to be due to eating food containing the fungus, the first step to take is to cease feeding such food. Affected animals should be given individual attention. They should be given stimulants, such as strong black coffee, whisky, brandy, &c., either with or immediately after the administration of raw linseed oil (1-1½ pints). Where gangrene has set in, treatment is useless and animals should be destroyed.

ACTIVITIES AT ROSEWORTHY AGRICULTURAL COLLEGE, 1933-34.

PART III.—CEREAL BREEDING, PURE SEED PRODUCTION AND VARIETY TRIALS.

[By ALLAN R. CALLAGHAN, D.Phil., B.Sc., (Oxon); B.Sc.Agr. (Syd.), (Principal), E. J. BREAKWELL, B.Sc.Agr. (Syd.), Plant Breeder), and S. R. KLOSE, R.D.A. (Field Officer).]

A full account of the objectives of cereal breeding, the manner by which they might be obtained, as well as a detailed programme for pure seed production at Roseworthy College formed the theme of an article published in the *Journal of Agriculture* for July, 1933. A thorough and careful revision of procedure was considered necessary in order to overcome obvious difficulties and replace obsolete methods with those of more recent development. With the changes it is expected that much time will be saved without fear of prejudicing the results, and indeed greater accuracy and precision is the guarantee given by using analytical methods based on sound scientific principles. This applies particularly to the plant breeding methods, the conduct of trials to test the comparative worth of new crossbreds and introductions, and well-known varieties. The scheme for the production of pure seed was based upon equally sound principles, but the chief consideration after intitial selection is the employment of plenty of sound common sense so that subsequent seed multiplication is free from as many possibilities of error and admixture as possible. While at the time the scheme was largely hypothetical in nature, from the results and encouraging experiences obtained last season full confidence in the applicability and efficacy of the changes has been established.

In the preceding report on the general farm work at the College a full account of the conditions prevailing throughout the season was given. The specialised work under review benefited greatly from the bounteous season enjoyed, high yields were obtained and considerable progress was made in all phases of the work. Many of the general observations made in reporting on the crops grown on the main areas of the farm apply to the cereals grown in the experimental field, with the exception that in the spaced rows the finishing conditions did not operate with the same severity as they did under field conditions. The variety trials, however, suffered, but the results obtained may be depended upon to be typical of ordinary field response under similar environment. Other features of the year were the phenomenal growth of straw, and almost complete absence of serious diseases.

The work reported hereon was practically all conducted in one field of about 40 acres marked on the College map as No. 4A, and included all operations connected with cereal breeding, the testing of crossbreds and new varieties, the yield testing of established varieties and the very important preliminary stages of pure seed production. The success of such work is very largely dependent upon proper co-ordination, and all phases are essentially inter-related, but for the purposes of this report, clarity demands that the three main issues be dealt with individually, consequently an outline of the year's work in cereal breeding precedes the progress report on pure seed production and the results obtained in the variety trials.

CEREAL BREEDING.

With the wheat industry in a devitalised state, active and generous interest on the part of farmers in wheat breeding problems has declined, yet at the moment the value of any variety which may claim to increase the cash returns of the grower would probably be a greater boon to the farmer than any artificial

stimulus that might be administered as a temporary expedient. Any increase in cash returns per acre strikes at the very root of the trouble, operating as it does as a credit offsetting the burden of acreage costs.

From the national point of view, therefore, wheat breeding retains its prideful position of importance; for it to wane in keeping with the decline in vigour of the industry would be fatal and disastrous in the long run. Progress is slow, but once a full and comprehensive programme is in active operation results come with regularity, varieties are evolved to overcome certain diseases, to suit certain soils, certain seasonal conditions and to fill certain specific requirements. The first and foremost necessity is therefore to plan the work well ahead, with breadth of vision, and obtain material from which the various types might be selected. In order to build up a more comprehensive population of types and strains from which to select, a large number of crosses were made during 1933. These numbered fifty and have already been listed in the *Journal* for March 1934. The objective of all crosses is to gain a variety or varieties which will increase the monetary returns of those concerned in the industry. Actual prolificacy, or, the power to yield well, in itself does not fulfil this requirement for inherent high yielding ability is very often accompanied by defects such as poor milling and baking quality, susceptibility to disease, weak straw, or tendencies to shatter, any one of which may be quite sufficient to condemn a variety for general cultivation. In summating, therefore, the cross-breeding programme has as its object the combination of high yield with the attributes of disease and drought resistance, at least average quality, strong straw and non-shattering characters, thereby attempting to meet the demands for higher net returns.

With accurate technique, it is now possible to obtain a high percentage grain setting from flowers cross-fertilised, and, last year, with the avowed object of saving a generation, if possible, more flowers than usual were operated upon in the case of each cross; consequently a larger number of crossed grains was obtained. Under these circumstances it was possible to utilise some of the grains obtained from each cross in an endeavour to grow them through the summer months; in the event of failure ample grain was retained for growth at the normal time. The seed used for the interim crop was sown in a bird-proof enclosure, growth was maintained by irrigation whenever necessary, and the plants were afforded adequate shelter from the heat of the summer by hessian shields. Last summer was particularly severe, especially during the closing months, but the first generation (F1) seed sown

in December made remarkable growth, and yielded a surprisingly large amount of second generation (F2) seed. By this method two generations were obtained in one year, and valuable time thereby saved. It is not possible, of course, to grow other than F1 seed under such conditions, but the saving of one year in the production of new forms is quite a consideration. As a result of this approximately 70 crosses in the second generation were sown this year; thus within a few years there should be a large number of valuable lines in advanced generations. It is not feasible to expect the evolution of a good commercial variety from every cross; indeed, all crosses are not made with this immediate objective. Certain varieties may be crossed in an effort to obtain material possessing a combination of such characters as will be of value in breeding work in the future, although of no direct economic importance. This is merely a process of building up with the ultimate idea of grouping as many desirable characters in the one variety as possible.

The importance of careful selection from hybrid material is not generally realised, but it is the very basis of successful plant breeding work. Too often the layman is inclined to look upon the simple manipulations involved in making the cross as the very essence of the plant breeder's skill when, in point of fact, it is merely the foundation for the more important selective work to follow. The success or failure of any cross-breeding project is definitely dependent upon the selections which are made from subsequent generations; the ultimate value of lines produced is controlled by such selection. At the present time there are approximately 30 crossbred populations in a more advanced stage than the second generation. These were all subjected to rigorous selection during the season, a procedure which considerably reduced the number of inferior lines therein. The basis of this selection is simply the isolation of the best plants in every population. It is imperative, therefore, that every plant should be given an equal chance to express its characters; hence the necessity for careful space planting and uniform width between rows. The best plant does not necessarily mean the most spectacular, nor even the most vigorous. One particular plant may be especially robust. It does not follow, however, that its possibilities for yield are in keeping with its outward expression. Other characters require consideration—firstly, simple morphological characters, such as straw strength, height and fineness of straw, grain holding ability, and other characters of agronomic importance. By careful scrutiny and the spontaneous recognition of what is actually required, selection along these lines becomes a matter of systematic observation. From the viewpoint of physiological characters, such as disease and drought resistance, the problem is more involved. Seed of nearly all crossbred lines is artificially inoculated with spores of flag-smut and bunt each year, and single plant selections are, as far as possible, made only from lines resistant to these diseases. In this regard a rust epidemic to the plant breeder becomes a blessing in disguise, and through the medium of such some very useful selections can be made which would otherwise be impossible. In such cases the disease itself becomes the agent of selection. In fact, the wheat breeder is at a decided disadvantage in selecting for rust resistance unless rust occurs frequently. To overcome this, artificial means of inducing rust have to be resorted to in an attempt to save time and prevent the continuance of lines which may ultimately succumb to the ravages of the disease. Facilities are being provided at the College this year whereby at least mild epidemics of rust may be induced every season under more or less controlled conditions. This merely entails the provision of suitable conditions of humidity at certain periods of the year.

Selection for drought resistance falls into a similar category, and years such as the present afford the breeder excellent opportunities for vigorous culling of lines which are unable to compete with others grown side by side under the same adverse conditions. In this respect a drought year may be the means of eliminating much unsuitable material.

Having given due consideration to the simple morphological and physiological characters, attention is next directed to baking quality. Unfortunately this cannot be assessed in the field. All promising lines, however, are tested in the laboratory, and the figures for baking quality thus obtained are recorded, and form an important basis of elimination. A detailed description of the methods employed in selecting for baking quality appears in the *Journal* for July, 1934.

In spite of the fact that initial selection is based very largely upon apparent yielding capabilities, the actual assessment of yield can only be made in later generations. It is in the comparative yield tests conducted at this stage that a large percentage of crossbreds falls by the wayside. Even the most skilled observer cannot be sure of selecting only high yielding lines when the first selections are made.

Yield testing is carried out from the fourth to the seventh generations on a small scale in the hand plots. All promising lines are then promoted to field trials, where they are tested for at least three years in comparison with standard varieties. Unless a new variety is able to outyield the standard variety of its maturity class over a number of years it is not likely to establish itself favourably and permanently in competition with varieties already grown. For this reason it should not receive further encouragement. Refusing it a name and dropping it forthwith is a wise precaution against its possible release and subsequent swelling of the ranks of the already far too numerous mediocre varieties.

Of the crossbreds in advanced generations at the College (Ford x Merredin)[5] and (Ford x Carrabin)[5] are promising; high quality lines, possessing good agronomic characters, being present in both crosses. These are now being tested for yield. Unfortunately it is only in very recent years that the need in Australia for better quality wheats has been fully realised; hence most of the crosses made in the past have given rise to material deficient in this character. Although some of the crossbreds on hand may have produced some quite good varieties from the point of view of yield, the present policy demands that any new productions which do not possess baking quality at least superior to such types as Nabawa and Gallipoli should not be distributed. On this account many otherwise promising lines were rejected during the season.

Crosses which produced lines of at least fair quality are (Onas x Nabawa)[4], (Nabawa x Canberra)[4], (Ford x Gloss)[4], and (Gloss x Florence)[5]. All such lines have been retained, and will be carefully observed for agronomic characters and tested for yield and disease resistance.

Several improvements are to be inaugurated into the plant-breeding work this year. These include the growing of drill strips of the advanced lines of crossbreds, interspersed with strips of standard varieties in order that the field behaviour of these lines may be studied and compared with that of the established varieties. A more extensive system of yield-testing varieties and crossbreds in the hand rows has been adopted, and these yield-tests will serve as a forerunner to the field trials, and no variety will be promoted to the latter without the fullest qualifications. An active policy of introduction of new varieties from other States and countries has been maintained. Such introductions are subjected to close observation, and their direct commercial value or their indirect value in breeding work estimated.

While it is unreasonable to expect the evolution of the perfect variety, small improvements from year to year should be possible once the present programme is in full swing. It is by such improvements that the margin of profit in wheat growing is increased, and the Australian farmer placed in a better position to meet overseas competition.

Trials with grazing oats are also being conducted, and a progressive programme of barley and oat breeding commenced.

PURE SEED PRODUCTION.

The production of pure seed is a very important function of the College. Seed of all common varieties is distributed to the farmer as true to type and as free from admixture as possible. The foundations for this are dependent upon careful selection of high-grade plants, and the propagation and increase of the resultant seed from year to year. All chances of contamination are minimised, and all varieties are subjected to the strictest scrutiny, so that the seed offered for sale each year may be of the highest standard possible. The pure seed programme being conducted was introduced in 1932, and was fully explained in the *Journal* (July, 1933). The general working of the scheme has been fully tested and found to be both practical and efficacious.

One important aspect of pure seed production might be mentioned at this juncture. Actually the College attempts to supply the requirements of farmers to the fullest extent, but it must be realised that many miscellaneous varieties which are considered inferior to other better known and more useful ones have to give precedence to the latter, otherwise our College areas would be devoted largely to varieties definitely unsuitable to the environment in which the work is carried out. As it is, more varieties are grown on the Farm than is considered necessary so that these demands may be filled. By doing this, the average College yields are appreciably affected, but the general policy in mind is to concentrate on varieties considered to be the most useful to foster throughout our wheat lands.

During last season careful single plant selections were made from all common commercial varieties, but special attention was given to the following because of their popularity and general usefulness and because their present variability offers a genuine field for substantial improvement:—

Sword.—There appear to be three strains in the commercial Sword—a plump grained, a shrivelled grained, and a purple strawed type. Unfortunately the season was such that the purple straw was not obvious, and hence this type could not be rogued from the pure seed rows with any certainty. A very noteworthy observation made during the year, however, was that plants possessing purple straw have a decided tendency to snap off at the head; the consequences of this are obvious. Bearing this in mind, a block about 50 yards of one of the pure seed rows was carefully rogued of all plants showing this weakness, and the resultant seed should give rise to a line containing very few purple strawed plants. Roguing the pinched grain type was also difficult, as this only appears in adverse seasons. Both these strains undoubtedly have a deleterious effect upon yield, and their elimination, which is in progress, will greatly enhance the value of this variety.

In the meantime the present sample of Sword sown in the stud plots is sufficiently good to warrant its continuance as pure seed; indeed, it is probably a distinct improvement over any commercial Sword in the State.

Ford.—Many crops of Ford show considerable diversity in type, but lines were isolated at the College last year which comply in all details to the true Ford, and contain none of the inferior strains. Small amounts of high-grade Ford should be available in the coming harvest, and there should be an abundant supply of seed by the harvest of 1935.

Nabawa and *Bencubbin* were also subjected to careful selection, as these two varieties show some undesirable variations, especially in height and maturity.

A detailed description of selection for quality within the varieties has been given in the July issue of the *Journal*. This is a sideline of pure seed production, being an endeavour to isolate the highest quality strain of each variety.

The long rows, which form the second year of the pure seed programme, produced a heavy yield of grain of high standard, thus enabling a large area of "stud"

seed to be sown this year. Likewise, the "stud" plots also yielded well, so that, given normal conditions, a reasonable quantity of seed of the most important commercial varieties should be available for distribution for the seeding of 1935.

WHEAT VARIETY TRIALS.

In reporting on the variety trials conducted at the College last year due cognisance must be taken of the system in operation over the past five years. Last year's results actually form the culmination of a scheme which was inaugurated in 1928, when the intention was to determine the relative yielding ability of the many numerous varieties under cultivation in the State. There is no question that there are far too many varieties grown in South Australia, and a more intelligent choice should ultimately increase the State average yield. The idea which prompted the scheme originally aimed to illustrate the advantage of some varieties over others, in the hope that conclusive evidence would gradually eliminate all inferior varieties and increase the area devoted to those which will give higher and more reliable returns per acre.

The objective was, firstly, to illustrate the relative merits of certain varieties under College conditions which are typical of conditions in the better class Mallee soils of the State; and, secondly, to show the incapacity for yield of certain varieties which are fairly extensively grown.

The secondary objective, viz., of eliminating undesirable varieties, has been completed with the results of last season. During 1928-30, 58 varieties of wheat were sown in the yield trial. In succeeding years those which came or which were likely to come into general cultivation were added to this list and tested. In all 77 varieties, as well as numerous crossbreds and selections, have been tested for one or more years. The net result is that since the inauguration of the trial only 10 of the 58 have survived.

The original scheme of testing was to grow each variety in three one-third acre plots, distributed at random throughout the field. This was done in order to minimise discrepancy in results, due to soil heterogeneity. From each of these blocks a hay cut was taken and the rest allowed to mature for grain and harvested for such. By averaging the yields from each plot and reducing to a per acre basis the yield per acre of both hay and grain was obtained.

In 1933 the method was changed somewhat, and five one-twentieth acre blocks were used for each variety. These blocks were about 8ft. wide and 4½ chains long. No hay was cut, the whole of the block being harvested for grain. In the future hay wheats will be tested separately, and dual purpose wheats will be included in both hay and grain trials. This method will save considerable labour and space. Five replications of each variety should give an even more accurate interpretation of its behaviour under field conditions than three replications, in spite of the fact that the size of the plots has been considerably reduced.

Statistics, specially devised for such purposes, have illustrated that the yield test experiment, as conducted at the College last year, was remarkably accurate. The standard error for the experiment was only 42lbs. per acre in the case of late varieties and 59lbs. per acre in that of early and mid-season varieties. This means that on the figures for 1933 for the late group, if one variety outyields another by 84lbs. per acre (or twice the standard error) it may be considered as a significantly better variety, and the chances are about 30 to 1 that, under similar conditions, it would outyield the second variety again. If one variety significantly outyields another over three or more years we can definitely state that it is a superior variety. The use of statistics in field tests may appear to be superfluous, but it safeguards against making incorrect conclusions, and gives a measure of reliability to the tests.

TABLE I.—*Summary of yields of varieties tested* 1928-33 *and of all varieties tested in* 1933.

Variety.	1928.		1929.		1930.		1931.		1932.		1933.		Mean 1928-33.		Position 1928-33.	Position 1933.

In Table I. the results for 1933 are shown, together with results from past seasons, for those varieties which have been tested since 1928. It will be seen that a few of the newcomers, particularly Gluyas (R.A.C.), Ex Fay 8, and Bencubbin gave yields superior to those of some of the established varieties. These will be subjected to further yield tests in an endeavour to substantiate these results.

Unfortunately the practice in the past has been to group all varieties together, irrespective of the time of maturity. This detracts somewhat from the value of the results. For this reason the summaries in Table II. *et seq.* have been divided into early, mid-season and late groupings, and the varieties placed into their respective groups and compared with the standard variety for that group.

This year varieties have been grouped together according to maturity and the groups sown at the correct time. By this method a more direct comparison will be obtained, and farmers in the late districts, for example, will be able to compare more readily the behaviour of varieties which are common to their districts.

SUMMARY OF 1933 RESULTS.

Nawab was again the leading variety, closely followed by Sword and Waratah. Gluyas (R.A.C.) was promising. Others to show to advantage were Sirdar, Ex Fay 8, Bencubbin, Regent and Ford. Florence was disappointing, shattering largely accounting for the poor yield. The late maturing varieties, such as Gallipoli and Currawa, were sown too late to give their best yields. None of the crossbreds was outstanding. The severe finish was responsible for a substantial decrease in yield, particularly with the late varieties, but it was gratifying to see Waratah yielding so well under adverse finishing conditions. One of the criticisms previously levelled at Waratah was that it lacked the capacity to finish well under such conditions, but last season did not substantiate this hypothesis.

Grouping the varieties into mid-season to late and early to mid-season groups and applying the analysis of variance method to interpret the results statistically, the following conclusions were arrived at:—

1. *Late Group.*—Nawab is by far the best yielder in the group. Sirdar is not significantly better than D.G.H., Gallipoli, Collection and Currawa, between which varieties there is no difference.

2. *Early and Mid-Season Group.*—There is no difference between Sword and Waratah, although the former is significantly better than Gluyas (R.A.C.). These three varieties are all superior to Ex Fay 8, Regent, Bencubbin and Nabawa x Gluyas Q.O.98, between which there is no difference. Bencubbin is superior to Nabawa, which is about equal to Florence. Nabawa is not significantly superior to Nabawa x Hurst's 2, but the crossbreds Nabawa x Bunyip and Nabawa x Gluyas Q.O.29 are denfitely inferior, and Faun 3 is a failure.

Summaries of the yield test for 1928-1932 (inclusive) are given on Table II. *et seq.* These tables are more or less self explanatory, and the performances of any of the varieties tested can be compared with that of the standard variety for its group.

In some instances it will be seen that a variety which was superior to the standard in yield has been rejected. This is due to the fact that it possesses some very undesirable character, such as weak straw, poor grain samples, or some other defect. The low yield of Ford in 1930 cannot be considered as typical of the variety, and it is assumed that some small discrepancy in results escaped detection. Given a normal yield in this year Ford would occupy a much higher position than is shown in the summary.

Oat Variety Trials.—Results of trials with varieties of oats from 1928-32 (inclusive) are appended in Tables V. and VI. It will be seen that the popular variety, Algerian, leads in the hay trials, but Early Kherson, Early Burt and others have given more satisfactory results for grain.

It is fully realised that the oat crop is likely to extend considerably in South Australia, especially if more suitable varieties can be evolved, because, apart altogether from its value as a marketable commodity and as fodder in various forms, it has a definite place in our agriculture as a rotation crop. Apart from its grazing potentialities, which are great, it has its use on the farm as hay, grain, or silage, in all of which forms it is remarkably well adapted for conservation. An elaborate system of testing would be required if the relative merits of all varieties, taking into consideration all possible uses of the crop, were to be tested. Both grain and hay yields are of importance, but these alone are inadequate if the all-round desiderata of any variety are to be assessed. The grazing value is of particular importance, and from this point of view alone several factors require careful consideration. Rapidity of early growth, bulk of early vegatative growth, relative palatability, and last, but by no means least, powers of recovery all demand attention, and it is well known that varieties are very variably endowed with these attributes. To combine rapidity of early growth, bulk of early vegetative growth, good palatability, and excellent recovery power after grazing becomes the objective in breeding grazing oats. The position becomes more complicated, however, when the dictates of farmers' practice and requirements demand that such an oat must also have capacity to yield well for either hay or grain. The need is for a variety able to give satisfaction in all three respects.

There is, however, plenty of room for another class of oat variety. Some of the early maturing varieties, such as Palestine, for instance, are of especial value in that they may be sown on completion of wheat seeding. These fall into a separate category, for their grazing worth needs no consideration, and selection for such types aims at isolating rapid maturing, sparse stooling, thrifty types possessing good straw and panicle characters. Such types require testing as a separate group; they should not be compared with dual purpose varieties, such as Algerian and Early Kherson. In fact, farmers failing to discriminate between varieties may

seriously misinterpret the value of other oats for grazing by growing a good grain-yielding type of the group under discussion, such as Palestine, which is notoriously poor as a grazing oat, with minimum recuperative ability.

The foregoing actually summates the basis of work being undertaken with oats at the College, and during the present season grain, hay, and grazing characters are entering into the tests and trials of oat varieties.

SEEDING LISTS FOR 1934 SEASON.

The wheat varieties to be tested in the field replicates in the 1934 season are:—Baringa, Dundee, Ford (R.A.C.), Ford, Gallipoli, Bobin, Nabawa, Ranee 4H, Sultan, S.H.J., Minflor, Nawab, Sword, Florence, Waratah, B.F.G. 3003, Aussie and Merridin, Minflos and True Gluyas. Strains of Gluyas and Ford will also be tested against each other.

It will be noticed that there are a number of newcomers in the trial, and the behaviour of varieties such as Dundee, Baringa, Bobin and S.H.J., which are receiving a good deal of attention, will be watched with interest. The College is also endeavouring to test the common high quality wheats in order to determine which varieties possess the highest potential yield. High and medium quality wheats in this year's trial are Dundee, Ford, B.F.G. 3003 (a promising Queensland introduction), Aussie and Merridin, Minflos and S.H.J.

Oat varieties under review include Algerian, Guyra, Belar, Early Kherson, Early Burt, Sunrise and Fulghum.

The plots have been further reduced in size, and this season five one-fortieth acre plots will be sown to each variety. All possible precautions are being taken to minimise border effect, and the plots have been planned so that the sowing and harvesting may be done with a minimum of labour. Investigations have shown that plots of one-fortieth acre give results equally reliable as those from a bigger area.

Pending results from the hand plots, where they will be systematically tested for yield, no crossbreds have been included in this year's variety trials, and crossbreds will be grown in the field trials only when they have given a consistently good performance in the hand plots.

In all trials the efficient utilisation of time and labour is the objective, and no consideration will be given to any variety approaching mediocrity. Rigorous rejection is necessary if reliable results are to be obtained, and any variety which survives in the field trials to be conducted at the College must necessarily possess all those characters which would render it suitable and acceptable for general cultivation.

PASTURE IMPROVEMENT.

Experiments and Demonstrations Conducted in Co-operation with the South Australian Committee of the Australian Dairy Council.

[By R. C. SCOTT, Supervisor of Experimental Work.]

Early in 1931 arrangements were finalised under which the Department of Agriculture agreed to co-operate with the South Australian Committee of the Australian Dairy Council in a series of experiments designed with the object of economically improving the quality and quantity of pasturage available in the dairying districts of the State.

Under this arrangement a wide programme of work has been planned and has expanded from year to year until at the present time it embraces:—

A. Pasture variety investigations.
B. Pasture mixture investigations.
C. Pasture strain investigations.
D. Pasture manurial investigations.
E. Rotational grazing investigations.
F. Pasture demonstrations.
G. Pasture and Pasture Conservation Competitions.

In order to commence operations, dairymen were circularised inviting applications from those willing to assist in the detailed operations which are so essential if reliable information is to be obtained. The Committee undertook to supply the necessary seed and manure and, in a few cases where grazing records were required, they also assisted with the fencing material, whilst in return the experimenter selected provided all labour, kept particulars of the results obtained, and forwarded periodical reports indicating the progress of the trials. As often as circumstances permitted, Officers of the Department have inspected the plots, whilst members of the South Australian Committee have made an annual inspection of the more important trials.

PASTURE VARIETY EXPERIMENTS.

A collection of varieties has been planted at a number of centres, and the following men are co-operating with the Committee in this work:—

J. Fisher	Gladstone
F. Coleman	Saddleworth
W. S. McAuliffe	Eudunda
T. W. Roenfeldt	Greenock
W. T. Vigar	Eden Valley
A. E. D. Francis	Bugle Ranges
F. Keen	Meadows
D. F. Sheppard	Prospect Hill
J. B. E. Wright	Meningie
J. A. Carruthers	Narrung
J. H. Goyder	Long Flat, Murray Bridge
A. C. Kemp	Hatherleigh
W. K. Chambers	Mount Gambier
A. Leech	Warunda, Port Lincoln

Each pasture has been planted as a pure stand in small plots (generally speaking, about 1 square chain in area) in order to ascertain the type most suited to the soil and climatic conditions obtaining in the locality. In the poorer lands the seeding of a clover in conjunction with the grasses would, no doubt, have been of advantage, so far as the development of the latter is concerned, but at the

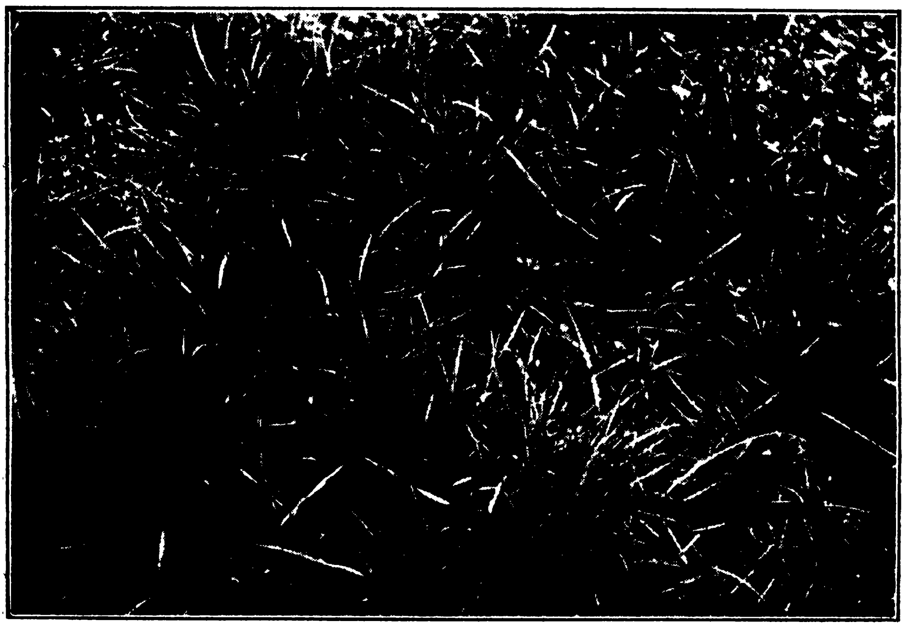
same time sufficient growth was made to allow for the forming of an opinion regarding their relative value. It does not appear necessary to give full particulars of all centres and all varieties tested, but information concerning the most useful is set out below.

Subterranean Clover (Mount Barker Strain).

This is far and away the most important leguminous pasture plant in this State, and in all plots situated in districts enjoying an annual rainfall exceeding 20 inches it made much superior growth to any other clover. It thrived in a great variety of soils, but is particularly dependent on adequate dressings of phosphatic fertiliser.

Subterranean Clover (Dwalganup Strain).

Although not yet fully tested, this early ripening strain offers great possibilities, as the legume which will fill the requirements of the 12 to 20 inch annual rainfall country. In the red lands of the North, in plots at Saddleworth, Eudunda, and Gladstone, it has made satisfactory growth; whilst in the Lakes area, namely, at Narrung, it showed to considerable advantage. So far as the sandy land of the latter district is concerned, this strain of Subterranean clover exhibited great



A good pasture mixture, comprising Perennial Rye grass and White clover.

promise, and can be confidently recommended for trial, not only in the localities mentioned, but throughout the agricultural areas generally. Its advantage lies in the fact that whereas the ordinary type Subterranean clover demands damp, late Spring conditions for full maturity of the grain in order that the plants can make provision for a new crop in the following year, the Dwalganup type matures its grain some weeks earlier, and thus escapes the adverse conditions generally experienced in late October and November in the 15 to 20 inch rainfall areas. In growth characteristics the early type is not as leafy as the Mount Barker strain, and, consequently, from a pasture point of view would never be seeded unless the climatic conditions rendered such planting necessary.

White Clover.

Two strains of white clover have been tested, namely, Certified New Zealand and Kentish Wild White. Neither has shown to particular advantage on our pasture lands generally, but of the two, the former appears to be the better type so far as the grazing of dairy cattle is concerned. At Eden Valley the Kentish has proved relatively persistent, but has not made any bulk of growth and tends to lie close to the ground. On the other hand, the New Zealand strain is a much stronger and more leafy grower.

The results obtained indicate that moist conditions and fertile soils are essential for this clover, otherwise it fails to make headway and does not persist throughout our long, dry summers. The best stands have occurred in the rich lands of the Murray Swamps, Mount Gambier, Mount Barker, and Mount Compass, and consequently it cannot be recommended for general planting throughout the pasture areas of the State. However, each field must be considered according to the conditions offering, and in many localities the inclusion of Certified New Zealand White Clover in the seed mixture to be planted in the richer, damper gullies would be of advantage.

Red Clover.

Very little in favour of this clover can be reported, as in most cases the plots seeded failed entirely. The exceptions were those on the Murray Swamp lands and at Dingabledinga. In the trials at the latter centre the Montgomery strain was planted. This type made strong, luxuriant growth, despite the fact that the soil was of low fertility, and, consequently, it is worthy of further testing. However, on the whole, Red Clover has not shown to advantage in these experiments.

Strawberry Clover.

This is a variety demanding special conditions, and, consequently, it is not surprising to find that in the majority of plots situated throughout the State the plants have failed to make headway. In those situated at Hatherleigh, where the soil is wet and of the black, sea mud type, Strawberry Clover was the best leguminous pasture variety, whilst in a damp gully at Meadows it has also done well. The results obtained indicate that in swampy locations, including those containing an appreciable quantity of salt, this clover is able to thrive, making strong growth of palatable fodder, but the planting should be confined to such areas, and it is not of particular value in the State as a whole.

Clustered Clover.

This annual clover has done well throughout the plots generally, although in the higher rainfall areas it has not yielded the same abundance of fodder as some of the other varieties. However, it is well suited to those districts in which the annual rainfall lies between 16 and 20 inches, and has given first class grazing returns at Nuriootpa, Eudunda, Saddleworth, Narrung, etc.

Lucerne.

In these trials lucerne has been seeded as a grazing crop. In the Adelaide Hills generally, and also the South-East, attack by lucerne flea has militated against the establishing of lucerne, but even where a good stand has been obtained it has not shown to advantage as a pasture plant. However, at Meningie and Narrung lucerne seeded on the sandy lands has yielded more grazing than any other variety, whilst in the plots situated in the agricultural areas north of Adelaide, and also of Southern Eyre's Peninsula, it has done extremely well.

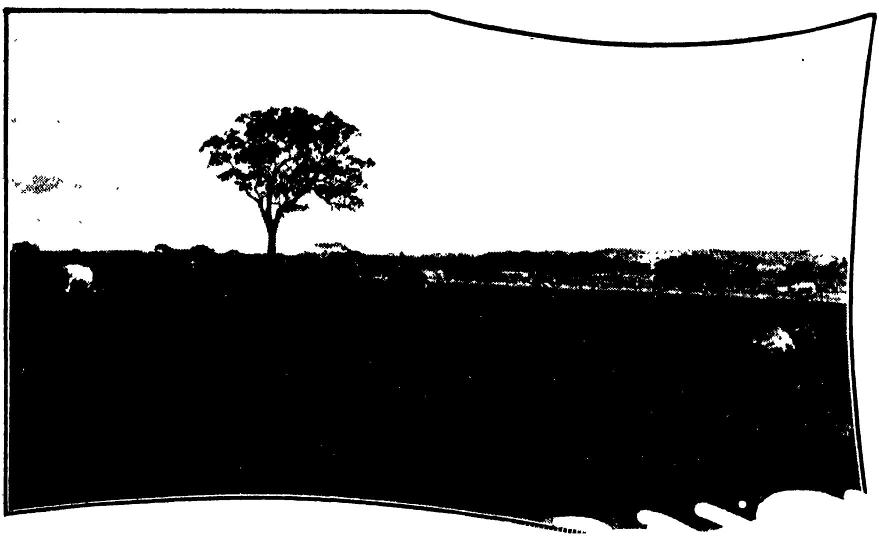
Perennial Rye Grass.

So far as this fodder is concerned, it is important to see that the best quality of seed available is utilised so as to ensure the production of leafy plants, possessing true perennial habits. Unless certified seed or grain which, to one's own

knowledge, has been harvested from old pasture stands, is planted, there is a danger that stemmy type plants will be produced which, in the course of two or three years, will die out despite the character of the soil or the climatic conditions experienced. The best Perennial Rye Grass plots have been those situated in areas in which the annual rainfall exceeds 20 inches and in which the soil is of a fertile nature. Under such conditions Perennial Rye Grass can be recommended, but it is a fodder demanding high fertility and, therefore, should always be seeded in conjunction with clover and liberally manured.

Wimmera Rye Grass.

Viewing the results from the point of view of the pasture areas as a whole, Wimmera has proved the most valuable grass included in the variety trials. Being a free seeding annual, it is not liable to extinction by a long, dry summer, whilst, unlike many other annual plants, it is readily consumed by livestock when in a dry state. Wimmera Rye Grass is particularly drought-resistant, and is able to flourish



Manurial Experiments on the property of Mr. George Cleggett, Mount Barker.

in much less fertile soils than Perennial Rye Grass. At Warunda, on Eyre's Peninsula, strong growth was made when seeded in very poor, shotty, ironstone country. In addition, it has done well in the lighter sandy land of the State, whilst it has also responded under favourable soil and climatic conditions. Comparatively with good stands of Perennial Rye Grass, it possesses the disadvantage of making more stemmy growth, not remaining green as long in early summer, not responding with fresh growth after every rain during the summer, and not making such rapid headway after the opening of the season in autumn. Nevertheless, under average conditions it is the best grass and would only be displaced by Perennial Rye Grass, *Phalaris tuberosa,* or Cocksfoot in the more favourably situated areas in the South-East and Adelaide Hills.

Phalaris tuberosa.

In these variety trials, *Phalaris* has proved a very useful fodder, but has made better growth and crowns in the heavier, more fertile soils than in the lighter, sandier land. Its chief feature has been its ability to withstand hard grazing and make rapid growth after the opening rains in autumn. Another important point which has been well illustrated in several instances is the necessity for thorough preparation of the soil if the variety is to be successfully established. The young

plants appear to be particularly susceptible to competition in the first few weeks of their existence, and are easily crowded out by weeds if a clean seed bed is not available. Providing that precautions of this nature are taken, *Phalaris tuberosa* may be recommended for extensive planting. It is very drought-resistant and has done fairly well under a 17 inch rainfall at Eudunda, but prefers heavy soils to those of a light nature.

Cocksfoot.

The most valuable of the remaining fodders is Cocksfoot, and of the various strains the Akaroa type has made the best pasture. This variety requires high rainfall conditions and has done well on the rich reclaimed soils of the Murray Swamps, although at the same time it has thrived in some of the lower fertility soils of the Adelaide Hills. As yet little has been done with Cocksfoot, but it is a variety worthy of more extensive trial in the wetter areas.

The pastures which have been discussed are the most important in the variety trials, but others included in the plots are Sheeps Burnet, *Danthonia pilosa*, Chicory, German Tall Fescue, Primrose, Timothy, Fox Tail, Crested Dogs Tail, Prairie Grass, and Meadow Fescue. However, none of these has shown to particular advantage and do not appear likely to prove of value.

PASTURE MIXTURES.

The pasture mixtures which have been planted as experimental plots and the centres at which they are located are as follows:—

Pasture Mixture.	Experimenter.	Centre.
Wimmera Rye Grass Subterranean Clover	W. T. Vigar A. E. D. Francis D. F. Sheppard F. Keen	Eden Valley Bugle Ranges Prospect Hill Meadows
Wimmera Rye Grass Early Subterranean Clover	F. Coleman W. S. McAuliffe T. W. Roenfeldt	Saddleworth Eudunda Greenock
Wimmera Rye Grass Lucerne	F. Coleman T. W. Roenfeldt J. A. Carruthers	Saddleworth Greenock Narrung
Perennial Rye Grass Subterranean Clover	W. T. Vigar F. Keen	Eden Valley Meadows
Perennial Rye Grass White Clover	A. E. D. Francis D. F. Sheppard	Bugle Ranges Prospect Hill
Perennial Rye Grass White Clover Subterranean Clover	Geo. Cleggett	Mount Barker
Phalaris tuberosa Perennial Rye Grass Strawberry Clover	A. C. Kemp	Hatherleigh
Phalaris tuberosa Subterranean Clover	W. T. Vigar A. E. D. Francis F. Keen D. F. Sheppard	Eden Valley Bugle Ranges Meadows Prospect Hill

Probably the best plot is that on the property of Mr. A. E. D. Francis at Bugle Ranges. This district has an annual rainfall of approximately 30 inches. The field planted possesses fairly good quality soil, but is not of the highest fertility. It is situated on the lower slopes of a relatively steep hill and has an easterly aspect, thus being fairly well sheltered from extremely cold conditions. Planting took place in 1932, 10lbs. of Certified Perennial Rye Grass and 5lbs. of White Clover seed, together with 2cwts. of superphosphate, being applied per acre. The field has been regularly grazed with cattle, whilst toward the end of last year the pasture was allowed to develop for hay and ultimately yielded 2 tons per acre. When both

the grazing and hay returns are taken into consideration, the annual yield from this pasture has been sufficient to maintain three-tenths of a cow per acre per annum and in the same year produce 1 ton of hay per acre.

In view of the fact that the pasture is only two years old, this is a very satisfactory figure, and, consequently, it is a mixture which can be recommended for conditions similar to the above.

On the other hand, the White Clover at Eden Valley, where the rainfall is from 4 to 5 inches lighter, did not persist; whilst on the poorer land of Meadows and Prospect Hill it has not made full development. Under such circumstances the addition of Subterranean Clover in place of the White Clover has overcome the difficulty, and a really good pasture secured.

In the manurial trials on the property of Mr. George Cleggett at Mount Barker a valuable stand of pasture has been obtained by including both these clovers with the Perennial Rye, whilst a little *Phalaris* was also added.

For average soil and climatic conditions in the Adelaide Hills a Wimmera Rye Grass-Subterranean Clover mixture can be recommended, and in at least one instance in these experiments an average grazing return exceeding half a milking cow per acre per annum was secured. In this connection 8 to 10lbs. of Wimmera

Phalaris and Subterranean clover hay.—A. E. D. Francis, Bugle Ranges.

Rye Grass and 6 to 8lbs. of Subterranean Clover seed should be sown if full returns are expected in the first year. However, if seeding at this rate cannot be afforded, the quantities may be approximately halved when the grower will be dependent upon the free re-seeding habits of these two fodders for thickening up the stand in the following year.

In the plots at Saddleworth, Eudunda, and Greenock, where the rainfall is lower but the soil fertile, the early strains of Subterranean Clover (Dwalganup) and Wimmera Rye Grass has made a satisfactory mixture. In this case 4lbs. of seed of the former and 6lbs. of the latter is ample. In those plots in which lucerne has been substituted for Dwalganup Subterranean Clover, the mixture has not been so successful. So far as the wet, black lands of Hatherleigh are concerned, the combination of Perennial Rye Grass (10lbs.) and Strawberry Clover (4lbs.) planted on the property of Mr. A. C. Kemp has led to the production of a dense mat of fodder and promises excellent results.

When properly established one of the best mixtures has been *Phalaris tuberosa* and Subterranean Clover, but experience has indicated that if a good stand is to be expected the seed of the *Phalaris* should be sown alone in the first year and the land to be planted very thoroughly prepared. In the following season the Subterranean Clover may be lightly cultivated in.

The seeding rates adopted under this method have been 4lbs. per acre of *Phalaris* and 6lbs. per acre of clover. Last year Mr. Francis at Bugle Ranges cut 3 tons of hay per acre from a plot laid down on these lines, and in addition secured a limited amount of grazing. In connection with the establishment of *Phalaris* it is interesting to record that a plot planted with seed has developed into a better stand, and with better crowned plants than an adjoining field planted at the same time with rooted sections. Provided the field is planted in the method recommended the above mixture promises to prove very successful in the heavier lands of the Adelaide Hills and South-East. However, so far as pasture mixtures are concerned, no definite recommendation regarding the best type can be made as everything depends upon the location and soil characteristics of the field to be planted.

Mr. W. T. Vigar's cattle grazing on a mixture of *Phalaris* and Subterranean clover at Eden Valley.

PASTURE STRAIN EXPERIMENTS.

Within comparatively recent years attention has been directed towards the importance of strains that occur in the different pasture species. Some of these variations are a distinct improvement upon the remainder, either from the point of view of the quality of the fodder (that is to say, more leafy in type) or better suited to special climatic or soil conditions. There is, therefore, work for the plant breeder to do in isolating and building up strains possessing such desirable characters until ultimately supplies of seed are available for distribution amongst growers in the pasture areas. Such work is in progress at Kybybolite Experimental Farm, under the control of the Manager, Mr. L. J. Cook, who is assisted by Mr. J. D. McAuliffe. The report prepared by Mr. Cook on these investigations is submitted below:—

"The plots of grass strains established in 1932 were maintained under field conditions throughout the season. Monthly notes were taken on their growth and general health. During the latter half of July careful examination of the winter growths of Perennial Rye strains were made and 122 individual plants pegged and noted. Fifty-nine of these were strains of New Zealand origin, 33 from Victorian, 28 from South Australian, and 2 from English origin. These plants were watched and noted during the rest of the season at various intervals.

All plots were grazed off short in mid-October. The subsequent summer growth of the ryes was somewhat poor on account of the light spring and early summer rains. However, at the completion of growth a further selection of plants was made, judged principally on the summer growth produced. Fifty individual plants were pegged, including 24 of New Zealand, 12 of Victorian, and 14 of South Australian origin.

It was noted that so far as Perennial Rye Grass plants were concerned, those plants which showed as good producers of winter grass were not always producers of good summer grass. However, some very nice leafy types of plants have been selected, and when observations have been continued over a number of seasons, it is hoped to isolate the most productive and persistent strains under our climatic conditions.

A small attempt was made to collect seed from a few of the better type plants, calico, glass fabric, and celaphone being tried as protection against cross-fertilisation by inferior plants. Where two plants of comparative equal type and quality were growing in close proximity they were covered together to allow for pollination. On account of the severe dry period experienced after the spring grazing, the plants seeded rather poorly and very little seed was secured from the isolated plants of Perennial Rye. A little from three strains was secured. The Perennial Rye Grass plots generally suffered by the long, dry summer experienced, only 120 points of rain falling from 5/12/33 to 3/4/34. From the latest examination of the plots, it would appear that the death of these plants during this period has been from 7 to 10 per cent. Better seeding results were obtained from *Phalaris tuberosa* species and small packets of seed were obtained from three strains: one, an erect, leafy type of growth; another, a very fine and thick leafy type, with good complete crowns; and a third of a robust, persistent type of local strain. Comparatively, the *Phalaris* strains withstood the dry summer better than the Perennial Rye strains, there being only 6 per cent. of deaths amongst plants.

The seven strains of Wimmera Rye grass sown in 1933 made very good growth throughout the season and showed quite a mixed variation of type in their growths. There was quite a noticeable difference in the period of growth of some plants, and the amount of leaf to stem varied greatly. Thirteen of the best plants were covered before flowering and their seed collected separately. Three selections were made from the Appila strain, two each from the Hampstead strains, one from the Wayville, and one each from the Turretfield strains.

Seven strains of Subterranean Clover were grown in small plots, and showed quite distinctive differences in their period of growth, amount of leaf and stem development, and quantity of seed produced. Our local strain of Shepherd's seed was outstanding as the best yielder of both bulk of growth and seed produced. The type from Bacchus Marsh was the best of the others, whilst the early strain from Dwalganup and Daliak made very poor development. The strain of pinkish stemmed clover from Springhurst made quite a lot of growth, but lacked in leaf development, comparatively, to the amount of stem growth. Seed from all of these strains was collected for further trial.

Of the other species of grasses tried in small plots during 1933, they mostly made fair growth under protected conditions, but none showed to greater promise than the *Phalaris* and Ryes. Crested Wheat Grass, grown from seed supplied by the Waite Research Institute, made a very fair stand, and grew quickly following the autumn rains of this year. Seed was collected from this species, and a trial of this under field conditions will be made during 1934.

Tall Fescue made the best showing of the Fescues, and Prairie Grass was the best of the Bromes, but these would not appear to be successful under field conditions. Some germination of *Danthonia* species, supplied by the Waite Research Institute, was secured, and the development of those will be watched and noted during their second year of life.

WORK FOR 1934-5 SEASON.

Observations and notes will be continued to be made of the 1932 and 1933 sowings of Perennial Grasses, including several notes of all plots, and special notes on individually pegged plants. It is proposed to sow the annuals, Wimmera Rye and Subterranean Clover, again in fresh plots, and to sow the selections under isolated conditions. Three acres of fallow have been well prepared, and the selected Wimmera Rye will be sown in islands amongst drills of oats. The selected strains of *Phalaris tuberosa* will be planted in isolated positions in corners of other fields, where it can be hoped that they will not be subsequently affected by fertilisation from annual and inferior types of canary grass. A small quantity of netting and fencing may be required to protect these at certain periods, but we confidently hope to commence from these as a nucleus a supply of first quality selected seed.

I wish to record the good assistance and careful work done by Cadet J. D. McAuliffe."

PASTURE MANURIAL EXPERIMENTS.

Two series of permanent pasture manurial experiments are in progress, namely, one conducted by Mrs. C. Milne at Meadows, and the other by Mr. G. Cleggett at Mount Barker. In addition a number of miscellaneous trials have been made in the form of treating unfenced strips across various fields, but in this case any differences are simply a matter for observation. However, so far as the permanent plots are concerned, each field is fenced separately, and, therefore, a complete grazing or harvesting record is obtainable.

MISCELLANEOUS EXPERIMENTS.

Most of the demonstrations relate to the influence of applications of sulphate of ammonia, whilst at Narrung various treatments connected with the handling of lucerne pasture were tested. Whilst considerably increased growth of fodder followed the ammonia applications, it is very doubtful if such applications were economical. However, one very interesting fact has arisen from these demonstrations, namely, the influence of sulphate of ammonia in encouraging drought resistance in Perennial Grasses. This is no doubt connected with the development of a strong and extensive root system, and is particularly noticeable on strips of Perennial Rye Grass. These strips carry a greater number of plants per unit of area than the adjoining land treated with superphosphate only, whilst, moreover, at the present time these plants are better grown and of more leafy nature than those on the next blocks, despite the fact that no ammonia has been added for two seasons.

On the other hand, the area of Wimmera Rye Grass (an annual plant) which was fertilised in a similar manner, only showed benefit in the year of application, and to-day no differences can be observed. It would appear, therefore, that sulphate of ammonia may have some value in assisting in the successful establishment of perennial pasture stands.

The other miscellaneous experiments were planned with the object of indicating the best method of treating lucerne planted for grazing purposes on sandy soil in the Lakes district. Various manurial dressings and other treatments were tested, and in each season the influence of winter tillage was most marked. The plots stirred in winter (in this case by harrowing) yielded more and better quality lucerne than the adjoining plots receiving fertiliser but no tillage. Consequently, tillage appears to be more important than manure, but maximum results can be anticipated when both are applied, and the experiments conducted on the property of Mr. J. A. Carruthers at Narrung indicate that an application of 1cwt. of superphosphate per annum, together with winter cultivation, is the best treatment for lucerne pasture under such conditions. However, whether superphosphate is available or not, the crop should in all cases receive a light winter tillage if full lucerne yields are to be anticipated.

PERMANENT MANURIAL EXPERIMENTS.

In both series four treatments are being tested, and at Meadows each block is 4 acres in area and at Mount Barker 2½ acres. The scheme drawn up aims at determining the influence of varying quantities of superphosphate, the effect and correct time of applications of sulphate of ammonia and the value of a dressing of agricultural lime. As the work has only been in progress for a limited time, no conclusions are available, but in future years interesting records should be secured.

MEADOWS EXPERIMENTS.

The area utilised for experimental purposes consists of flat country which becomes very saturated during the winter months, whilst the soil is a fine, whitish silt overlying a yellowish clay subsoil. In its natural state it carried red gum timber, but in earlier times many of the larger trees had been removed, and until recently the land was thickly timbered with red gum suckers. Prior to being set aside for this experiment the field was planted with Perennial Rye Grass, Subterranean Clover, and White Clover, but to-day the latter variety has practically disappeared, and the pasture consists of the two first-named fodders, together with a considerable quantity of voluntary herbage. The returns secured are shown in the following table:—

Manure.	Yield Per Acre.							
	Grazing.		Hay.					
	1932.	1933.	1932.			1933.		
	Cow Days.	Cow Days.	T.	C.	L.	T.	C.	L.
2cwt. superphosphate	45·5	78	2	4	56	1	0	0
2cwts. superphosphate, 1cwt. Sulphate of Ammonia (Autumn)	48·5	92·25	1	7	84	1	2	56
2cwts. superphosphate, 1cwt. Sulphate of Ammonia (Autumn), 1cwt. Sulphate of Ammonia (Spring)	74·5	119	2	15	70	1	7	56
2cwts. superphosphate, 1 ton lime (1932)	89·25	114·25	2	10	7	1	5	0

The grazing period has been taken over the calendar year.

Whilst no conclusions are possible, some interesting observations have been made, and under the wet soil conditions autumn applications of Sulphate of Ammonia appear to depress plant growth, whilst dressings in spring (August) have encouraged strong development, particularly with regard to the Perennial Rye Grass. The addition of 1 ton of Lime in 1932 has resulted in the production of good pasture, well balanced with grass and clover, which has yielded steady grazing throughout the year. The hay yields in 1933 were disappointing, as the dry, hot weather of October and November checked all growth, and the ultimate returns were much less than those anticipated when the cows were removed in early spring.

MOUNT BARKER EXPERIMENTS.

Mr. Cleggett's property is situated at Mount Barker Springs, and is one of the oldest farms in the State. The soil is of good quality and the average rainfall 32 inches per annum. A 10-acre field which had previously carried an oat crop was selected and planted with the following pasture seed mixture in 1932:—

10lbs. Perennial Rye Grass per acre.
5lbs. White Clover per acre.
2lbs. Subterranean Clover per acre.
2lbs. *Phalaris tuberosa* per acre.

An excellent germination followed, and a good stand, in which all varieties were represented, has been secured. However, wet winter conditions delayed the erection of the sub-divisional fences, and it was not until the late winter of last year that grazing records were obtainable. The various annual manurings being tested from this trial are:—

Plot 1—1cwt. superphosphate
Plot 2—2cwt. superphosphate
Plot 3—2cwt. superphosphate
1cwt. sulphate of ammonia (Autumn)
Plot 4—2cwt. superphosphate
1cwt. sulphate of ammonia (Autumn)
1cwt. sulphate of ammonia (Spring).

As grazing results are only available from September 1st no appreciable differences can be anticipated. However, the grazing to date is equivalent to carrying 1 cow per acre for 117 days on Plots 1 and 2 and for 120 days on Plots 3 and 4.

ROTATIONAL GRAZING EXPERIMENTS.

The difficulty in experiments associated with rotational grazing is to provide a comparison so that any improvement due to this system of pasture management may be readily measured. In this connection arrangements have been completed under which Mr. R. Magor, of Monteith, will supply the records of production from his irrigation block both prior to the adoption of rotational grazing and after it is in full operation. Mr. Magor is now subdividing his swamp block of 60 acres into 20 fields, so that when all fences are erected the milking herd can be regularly depastured on young, leafy fodder of high feeding value. At the present time a little over 40 acres are under sown pasture, consisting of a mixture of Perennial Rye Grass, Prairie Grass, and White Clover, and except for a small block of lucerne, the balance will be seeded as soon as circumstances permit. The full area will receive two dressings of superphosphate annually, one in Autumn and the other in spring, both being at the rate of 1cwt. to the acre. All returns from the property will be recorded, together with the details of the additional expense incurred under this system, so that figures will be available comparatively with those secured in previous years. As the conditions on the reclaimed areas do not vary appreciably from block to block, the conclusions arrived at from this experiment should be of value to a large number of men with holdings along the river.

PASTURE DEMONSTRATION FIELDS.

Examination of the records from the purely experimental blocks has shown a great similarity in the results obtained, while the number of useful varieties is relatively limited. Consequently, it was felt that an expansion of the work in the form of further experiments would simply be a duplication and little in the way of useful new information would be secured. On the other hand, if the knowledge already gained could be applied by means of planting what may be described as demonstration plots with the most suitable pasture mixtures, such plots would provide an illustration which other landholders in the district would follow, and thus lead to a general improvement in the pasture available. Accordingly applications were invited from men who proposed planting a pasture field in the following season. This field should not be too large but of such area as to allow for practical treatment under ordinary farm conditions, and, therefore, provide results which would be quite acceptable to the average landholder working under similar conditions. From the applications received plots were chosen and seed of varieties considered most suited to the soil and climatic conditions provided for planting. This scheme for the betterment of pastures has only recently been commenced, the

great majority of demonstration plots being planted in the present season; but it is felt that with publicity the fields established will be regularly inspected and serve as a guide for future planting in the various localities. Particulars concerning these fields are set out below:—

Demonstrator.	Area.	Approx. Rainfall.	Soil.	Seed Per Acre.	Manure Per Acre.

PASTURE IMPROVEMENTS COMPETITIONS.

The competitions inaugurated by the Committee have created considerable interest amongst all concerned, and the pasture mixtures or the methods adopted by the successful exhibitors in the handling of the crop or the conservation of the fodder have been closely examined by a large number of pasture men. In addition, a healthy rivalry has been created amongst the exhibitors themselves, and, consequently, such competitions are in the interest of the movement towards pasture improvement.

The competitions conducted include sown pasture, meadow hay, and ensilage competitions, and for this purpose the State is divided into districts with separate prizes for each. In the majority of cases arrangements have been made with the Department of Agriculture for the District Agricultural Instructor to judge the competition.

When making his award the judge reports on each entry, and consequently those reports and criticisms have considerable educational value. The results obtained and the remarks made have all been published from time to time, and therefore there is no necessity to repeat the particulars, but information regarding the scale of points under which the competitions are judged may be of interest.

Pasture Competitions.—Density of Sward, 30; Quality of Pasture, 25; Freedom from Useless Weeds, 20; General Management, 15; Area submitted, 10; total points, 100.

Meadow Hay Competition.—Suitability of Plants, 25; Curing, 25; Stage of Cutting, 15; Apparent Nutritive Value, 25; Storing, 10; total points, 100.

Ensilage Competition.—Suitability of Plants, 15; Succulency, 20; Palatability, 15; Nutritive Value, 35; Percentage of Waste, 15; total points, 100.

In connection with the nutritive value of the ensilage submitted, a sample from each entry was analysed and its actual feeding value determined.

ACKNOWLEDGMENT.

The success of any work of this nature is almost entirely dependent upon the efficiency and enthusiasm of the men conducting the various trials, and opportunity is taken of expressing the thanks of all concerned for the manner in which the different experimenters have co-operated in these tests.

It is also pleasing to record the assistance rendered and the interest shown by the Adelaide Chemical and Fertiliser Co., Limited, Wallaroo and Mount Lyell Fertilisers Limited, and Cresco Fertilisers Limited. These firms have made annual contributions towards the fertiliser required and their representatives have attended the inspection of the various plots.

QUALITY OF SOUTH AUSTRALIAN WHEATS.

[By C. E. Chapman, F.I.C., F.A.C.I., Deputy Government Analyst; and A. J. Farquhar, A.A.C.I., Chemologist, Department of Chemistry.]

[In recent issues of this Journal, the subject of "Baking Qualities of Australian Wheats" was discussed from the point of view of the wheat breeder. In this article Messrs. Chapman and Farquhar give the actual baking tests of various samples of South Australian wheats exhibited at the Royal Show, and have compared the results with the Pelshenke Test (or "Wholemeal Fermentation Dough Test," as they prefer to describe it) used by the wheat breeder.]

The quality of wheat is a subject of great importance to the milling and baking trades and one which, at present, is receiving a great deal of scientific attention in most of the wheatgrowing countries of the world. It is well known that some wheats yield flours that are admirably suited for making high quality bread whilst others are quite unsuitable for this purpose. The miller aims at producing a flour which will make a marketable loaf in any baker's hands; a flour of such high quality that, irrespective of the relative expertness of the baker, is able to produce a good quality loaf. It is what is known as a "fool-proof" flour. This means that the flour will stand up to fairly wide differences in treatment in the bread making process. It will make a good quality loaf if made with a slack dough or a stiff dough. It will stand a long proofing time without the dough collapsing or it will make a satisfactory bread with a shorter proofing period. Liberties may also be taken with a good quality flour in the knocking back process and moulding of the dough without seriously affecting the loaf. If our f.a.q. wheat would yield such a flour, the troubles of our millers and bakers would be ended, but unfortunately, this is not the case, as f.a.q. wheat as now supplied to the miller to make into flour does not nearly approach the standard indicated.

OBJECT OF THIS ARTICLE.

The object of this article is to show whether the quality of flour for baking purposes as assessed by the baking test agrees with the result arrived at by the wholemeal fermentation dough test on the same wheat.

As baking tests have been made on flours milled from 44 Competition Wheats exhibited at the Royal Agricultural Society's Show, and wholemeal fermentation dough tests have been done on the same wheats, a valuable opportunity is thus afforded to make a comparative and comprehensive survey of the results obtained by these two methods.

As the samples dealt with came from the Northern, Southern, Eastern, and Western parts of the State, they represent all the wheat growing areas, and, as they were entered in competition for prizes at the Show, one may assume that they represent the best wheat grown in the State.

The knowledge derived from the tests carried out on the samples should, therefore, be of value to anyone interested in South Australian wheats and the flours milled from those wheats.

WHOLEMEAL FERMENTATION DOUGH TEST.

A test for judging the quality of wheat which has come into use during the last few years is the wholemeal fermentation dough test. Pelshenke of Germany, and Cutler and Worzella of America introduced this test at about the same time in 1930-31. The tests as described by these writers are very similar in their application, the main difference being in the fineness of grinding the grain. Pelshenke, in his paper, "Contributions Towards Determining the Suitability for Baking of Wheat and Wheat Flours" (Arch. Pflanzenbau, 1930-31, 5, 108-51), describes the method of grinding as follows:—

"In the rough grinding of the wheat, the risk of "grinding to death" on trituration mills is extraordinarily great. For this reason disc mills are out of the question for the grinding of the wholemeal, as they cause too much heat owing to the enormous number of revolutions. It is, moreover, of great importance not to attack the grain with too much force and to obtain a wholemeal of as uniform degree of fineness as possible.

"The rough grinding of the grain is, therefore, done on a trituration mill driven by electricity on which the corn is ground between a frustrum of a cone fluted on the side, which is turned by a vertical axle and a fixed grinding mantle which is also fluted. The mill makes 80.5 revolutions a minute and the firmness of the wholemeal is regulated by the movable axle

"The grain is first rough ground coarsely, the mill being set wide. As the work of disintegration done by a mill is among other things dependent on the quantity of the grist poured on, the grain is poured on continuously from a kind of shuttle. The wholemeal obtained is then ground fine twice with closer fixing, first with fixing for medium fine grinding and finally with the closest fixing. In the last two grindings the grist can all be poured on at once. It is essential that the wholemeal passes the mill without stopping it up. This can be obtained by a suitable scheme of grinding. According to the experience of the milling trade, the degree of fineness of the wholemeal and in particular of the outer parts becomes greater as the proportion of moisture contents increases. One must, therefore, be careful that the samples contain approximately equal amounts of water."

The trituration mill is similar to that described in the Fisher Scientific Company's Catalogue—8-445.

Cutler and Worzella do not work on such a finely ground meal. They grind in a Wiley mill to pass a 1 millimetre sieve having circular holes. This mill yields a much coarser meal than that given by the Pelshenke grinding process. As the Wiley mill is not procurable in Australia, an ordinary coffee mill is used in its stead.

The wholemeal fermentation test will not be described here, as it has been fully dealt with in the June number of this *Journal* (A. R. Hickinbotham, B.Sc., &c., Chemist, Agricultural College, Roseworthy, page 1450).

An interesting comparison of the results given by Pelshenke and Cutler and Worzella tests on the same wheats is shown in the table on next page. Almost without exception the Pelshenke test gives a much higher test number.

TEST FIGURES.

No.	Variety.	Pelshenke Test. Ground in Trituration Mill.	Cutler and Worzella Test. Ground in Coffee Mill.
1	Quality	294	196
4	Quality	244	150
8	Quality	186	115
9	Florence	270	191
3	Comeback	352	231
7	Pusa No. 4	320	274
12	Bena	39	35
11	Nabawa	61	44
13	Nabawa	134	88
14	Nabawa	73	59
15	Nabawa	46	46
16	Nabawa	286	138
17	Nabawa	47	31
18	Nabawa	55	38
21	Nabawa	55	40
22	Nabawa	70	64
23	Nabawa	69	60
24	Nabawa	51	42
26	Nabawa	63	54
25	Gurka	36	34
27	Ford	168	129
34	Ranee	35	24

The coarser grinding has the advantage of giving a much shorter time test, and as coffee mill grinding has been adopted by other chemists in Australia we have adopted this method of grinding in order that a comparison of the figures obtained in this department may be more conveniently compared with those of other observers. Where time tests are given in this paper without being specified, they refer to the Cutler and Worzella method and not that of Pelshenke. In Australia it would be, in our opinion, as well for chemists to drop the term "Pelshenke Test" and agree to call it "The Wholemeal Fermentation Dough Test."

EFFECT OF VARYING THE AMOUNTS OF WATER IN THE DOUGH.

The effect of varying the amount of water in the dough ball was tried on a sample of Gurka wheat with the following results:—

Water added.	Time test.	Water added.	Time test.
2.7 ml.	30 31	3.0 ml.	33 33
2.85 ml.	31 33	3.5 ml.	34 34

By increasing the amount of water to mix the wholemeal into a dough, the time test on this sample of wheat gave a higher result, but the difference is by no means very great, as it is within the limit of error allowed by the test, *viz.,* 10 per cent.

TEST AFFECTED BY MOISTURE CONTENT OF WHEAT.

Greater differences in the results were obtained by increasing the amount of moisture in the wheat prior to grinding as shown by tests made of the following wheats grown in 1933-34 season:—

Variety.	Moisture. Per cent.	Test Figure.	Moisture. Per cent.	Test Figure.
Minister	9.4	93	13.4	103
Quality (bleached)	9.4	33	12.5	44
Quality	10.0	47	13.7	55
Florence	9.8	46	13.3	50
Baringa	9.9	32	13.2	38
Standard milling blend	10.6	45	13.7	50
F.A.Q.. 1933-34 (S.A.)	9.9	26	15.0	33

The age of the wheat also appears to have some influence on the time test, the older the wheat the longer the time of the test.

MILLING THE WHEAT.

The moisture in the wheats when received in the laboratory varied from 12.0 to 14.2 per cent., and before proceeding with the milling, they were all conditioned to 14.0 per cent. of moisture except the one having 14.2 per cent., which was milled without any adjustment of the moisture being made. A Simon's experimental milling plant was used to mill the samples, 2,000 grams (4.4lbs.) of wheat being taken for the test.

In the milling process, in order to obtain quantitative results, it is necessary to take out the sieves when the semolina has all been ground into flour, as there always remains a residue on the silks which has to be carefully removed and the final separation of the pollard and flour from this residue is made by means of hand sieving. The material remaining on a No. 10 silk is regarded as pollard and that which passes through the silk as flour. The point at which to leave off the hand sieving is controlled by making a number of trials of the colour of the flour passing through the silk. When the flour begins to show signs of being discoloured by particles of pollard, the sieving is stopped and the material remaining on the sieve is weighed as pollard, and that passing through the No. 10 silk is weighed as flour.

THE BAKING TEST.

It is generally agreed that, for bread making purposes, the best method of judging the quality of flour is by means of a baking test. This test is carried out under rigidly standard conditions so that each flour is treated in exactly the same way. We have adopted the tentative method of the American Official Agricultural Chemists with one slight variation. Instead of adding 58 per cent. of water to every flour, we add the amount of water which the flour will absorb, as previously determined by the water absorption test.

Ingredients.—

Flour: Weight equivalent of 85g. of dry flour, or 100g. of flour on a 15 per cent. moisture basis.

Yeast: 3g.

Sugar (sucrose): 2.5g.

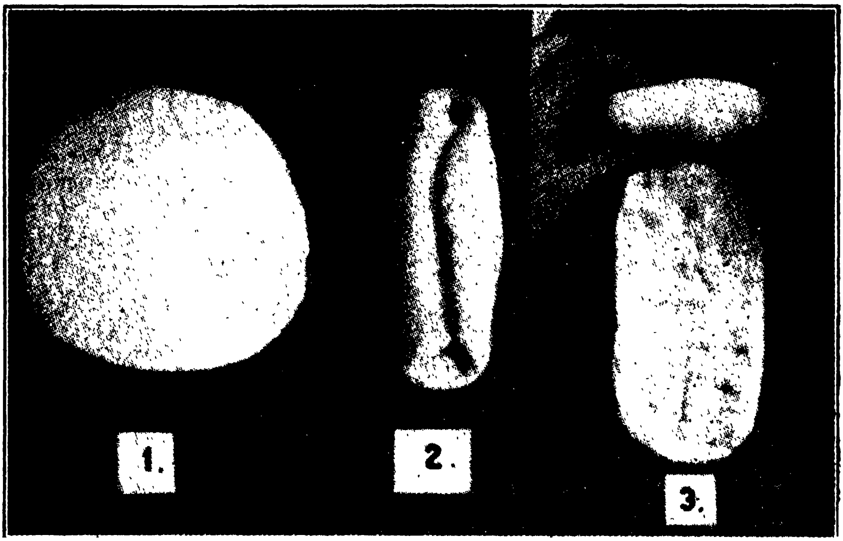
Water (distilled): Sufficient to make the water absorption of the flour as previously determined by the water absorption test on a flour of 15 per cent. moisture basis.

Mixing.—Dissolve the salt and sugar in a portion of the water. Disintegrate the weighed portion of the yeast in the salt-sugar solution or in another portion of the water. If the former procedure is followed, do not allow the yeast to remain in the salt-sugar solution for any considerable time before adding the flour. If stock solutions are used, correct for the water added. Add the flour, and mix with a flexible spatula that will conform readily to the shape of the bowl, making 125 cuts with the spatula. So regulate the temperature of the ingredients that the dough comes from the mixing operations at 30° C. Remove the dough from the bowl and fold 20 times in the hands.

Fermentation.—Place the dough in a fermentation bowl and allow to ferment for 105 minutes at 30° C. (plus or minus 0.5°) and not less than 75 per cent. relative humidity. Remove the dough from the bowl, fold 15 times in the hands (first punch), return the dough to the bowl, and allow fermentation to proceed as before for 50 minutes. Again remove the dough, fold 10 times (second punch) and place in the fermentation

bowl for 25 minutes. Remove the dough from the bowl, mould, and pan as follows:—

Moulding and Panning.—Place the dough on a table or moulding board and pound vigorously with the heel of the hand until the dough is flat and circular (Fig. 1). Holding one side of the dough, cut the mass loose from the table with the spatula, and turn on the reverse side. Fold over two opposite sides so that they overlap to a considerable degree (Fig. 2). Turn the dough over, and again pound it flat with the heel of the hand. Holding one end, cut the dough loose from the table with a spatula and turn on the reverse side with the seam of the dough running from the



Preparing the Dough for Panning.
(From Methods of Analysis A.O.A.C., U.S.A.)

operator. Starting at the more remote end, roll the dough toward the operator, folding it as tightly as possible (Fig. 3). Seal the seam tightly, and, with the seam underneath, seal the ends by pinching them vertically. Roll lightly under the palm of the hand, adjusting the dough to the length of the pan, and place in the pan with the seam down. (The length of the dough prior to the final light rolling should not exceed that of the pan). Use no dusting flour in the moulding process.

Proof.—Proof 55 minutes under the same conditions as for fermentation.

Baking.—Bake 25 minutes at a temperature of 230° C. (plus or minus 5°) at the level of the top of the baking pan. (Precise control of temperature, both as to degree and uniformity, is essential).

Measurement.—Weigh the loaf and measure its volume 30 minutes after removal from the oven.

Photograph.—The loaves are placed in air-tight lever top tins overnight. The next morning they are cut, and marks awarded for general appearance, colour of crumb, flavour, texture, and pile, giving 10 marks for each, making a total of 50 points. After a little experience, a trained observer is able to assess the relative values of different flours.

PHOTOGRAPHS AND TABLE OF RESULTS.

The photographs of the loaves of bread were all taken at the same distance from the camera, the magnification being the same for all samples, thus enabling an estimate of the volumes of the loaves to be made by the reader. The loaves were cut to show the texture of the crumb.

The flours from the various samples of wheat are grouped together in their varieties so that a comparison of the results on the samples of the same variety of wheat may more easily be made. Directly under the photographs, particulars are given of the results of the wholemeal fermentation dough tests, baking tests, and other data of interest in connection with the samples.

Some very high results were obtained for the wholemeal fermentation dough tests, notably on samples No. 32, Ford, 338; No. 7, Pusa No. 4, 274; No. 19, Minflos, 250; and No. 3, Comeback, 231.

One would expect that if the time test is an indication of the quality of a wheat that the baking tests on these wheats would have shown to greater advantage over the other wheats having lower time tests. But this is not so, for many wheats giving much lower time tests produce much better bread. None of the flours from the four above-mentioned wheats yields a loaf that could be classed as being of high quality, for their volumes were all below 400 ml. and their baking scores were all below 40 points. A good quality flour should secure a baking score of 40 points or more. Only five of the competition wheats for the last show reached this standard; they were No. 1, Quality; No. 5, Merridin; No. 20, S.H.J.; No. 22, Nabawa; and No. 29, Ford.

The wholemeal fermentation dough test gives results which in some cases do not agree with those obtained by the baking test, for the times obtained by the dough test are not proportional to the scores obtained by the baking test. Some wheats giving a high dough test number are quite unsuitable for bread making, such instances being No. 8, Quality, and No. 9, Florence.

The outstanding wheat of those tested is undoubtedly No. 5, Merridin. This wheat was very easy to mill and yielded a high percentage of flour. It also made a satisfactory bread under varying conditions in the baking process, which is a property highly desirable in flour.

No. 20, S.H.J., is also a first class baking flour and may be classed as the equal of Merridin with respect to its baking quality.

The three samples of Ford can also be regarded as satisfactory from a baking point of view. Ford has a tendency for the crust to break away at the top, and it lost marks for this defect.

Quality; only one sample, No. 1, of this variety made a loaf of good quality. The texture of all the samples was fairly satisfactory, No. 8 being the poorest.

The loaf volumes of these flours are more or less poor; No. 1, which gave the highest test number, gave the highest baking score and the greatest loaf volume.

One of the most interesting sets of photographs and table of results is that dealing with the 12 samples of Nabawa wheat. The photographs of the loaves obtained from these samples explain the figures given for baking score without considering flavour, pile, &c. No. 26, which gave the loaf of greatest volume, is obviously of inferior texture when compared with Sample No. 22.

The dough test numbers show fairly good agreement with the results obtained for baking score, the outstanding anomaly in this series being numbers 16 and 22. One would expect No. 16, with a test number of 138 minutes and baking score of 39, to give a higher baking score than No. 22, the latter sample giving a test number of 64 minutes and a baking score of 40. Taking the results on the whole, however, those obtained for wholemeal fermentation time tests agree fairly well with those obtained for baking score, as determined by the baking test.

The volume of a loaf is by no means a true index of the quality of bread. Take the case of No. 35, Sword; this sample gave a loaf volume of 400 ml., yet it obtained the lowest baking score of all the 44 samples. Its texture had the appearance of honeycomb, and it obtained very low marks in other respects.

The samples of Bena, Sword, Waratah, Golden Return, Nuggett, and Gurka proved to be unsuitable for bread making.

The samples of Ranee were of poor quality, No. 34 being particularly bad. The latter sample had a low dough test number, was of poor baking quality, and very low in protein.

Attention is drawn to the fact that Merridin and S.H.J., the two flours that obtained the highest points in the baking test, gave results for dry gluten which were almost as high as those for protein (N x 5.7) obtained on these flours:—

	Merridin.	S.H.J.
Dry gluten	9.7	10.8
Protein	10.0	11.0
Ratio (dry gluten to protein)	0.97:1	0.98:1

In the majority of wheats tested, the ratio of dry gluten to protein was much lower than those obtained for these two wheats. This peculiarity may be only a coincidence, but it may be worth while following up this matter when other samples of wheat are tested.

SUMMARY.

1. The wholemeal fermentation dough test does not give results expressed in time (minutes) that are proportional to the quality of flour when judged by the score obtained by the baking test.

2. A very high test obtained by the wholemeal fermentation dough test does not necessarily mean that the flour obtained from the wheat will be of high baking quality.

3. The wholemeal fermentation dough test is of value to wheat experimentalists, as wheats giving a lower test than 35 minutes may be discarded, as they can be regarded as being of poor quality.

4. Although the baking test is one which is more or less affected by the personal factor, it appears to be at present the best test available for judging the quality of flour.

5. Different operators should obtain agreeing results provided the conditions of the baking test are rigidly adhered to.

6. The interpretation of the baking test, i.e., the awarding of the baking score, is more or less a matter of opinion, but different observers should agree to within 2 or 3 points.

We desire to acknowledge the assistance rendered by Lt. Col. G. D. Shaw, F.A.C.I., and Mr. A. H. Scarfe, A.A.C.I., who carried out some of the chemical analyses and baking tests in connection with this subject.

THE IMPORTANT PASTURE PLANTS OF SOUTH AUSTRALIA CONSIDERED AS TO THEIR IDENTIFICATION AND CHARACTERISTICS.

[By E. M. HUTTON, B.Ag.Sc., Field Officer.]

(*Continued from page* 1554.)

B—THE CLOVERS AND CLOVER-LIKE PLANTS.

All legumes belong to the large family *Leguminosae.* This family has three sub-families, and it is the sub-family *Papilionatae,* consisting of all pea-like plants, to which the clovers and clover-like plants belong.

The pasture legumes in the sub-family *Papilionatae* are herbaceous plants with flowers which resemble a miniature sweet pea. The seed is contained in a pod which varies from a straight one in the Bird's-foot Trefoils to a coiled one in the Medics. The number of seeds in a pod varies from one or two in the Melilots to as many as six in Lucerne. The seeds are kidney-shaped and vary in size from very

Fig. 21.—Seedling of White Clover (*Trifolium repens*) at different stages of growth. In 1 the seed leaves or cotyledons are shown; in 2 the first foliage leaf is seen to be simple; in 3 the ordinary trifoliate leaves have appeared. [From *Agricultural Botany* by John Percival.]

small in Clustered Clover to relatively large ones in Subterranean Clover. The first leaves which appear are smooth and rounded, and differ from the true leaves. (See Fig. 21.) In the majority the leaves are divided into three leaflets, each leaflet possessing its own little stalk. This trifoliate leaf is borne on a longer stalk, which always has a pair of small leaf-like processes or stipules where it joins the

main stem. (See Fig. 22.) The lengths of the three small leaflet stalks and the character of the stipules are important in identification. In the Bird's-foot Trefoils the leaf is divided into five leaflets, the two lower leaflets taking the place of the stipules which are absent. The general habit of the pasture legume—that is, whether annual or perennial—is also important in identification.

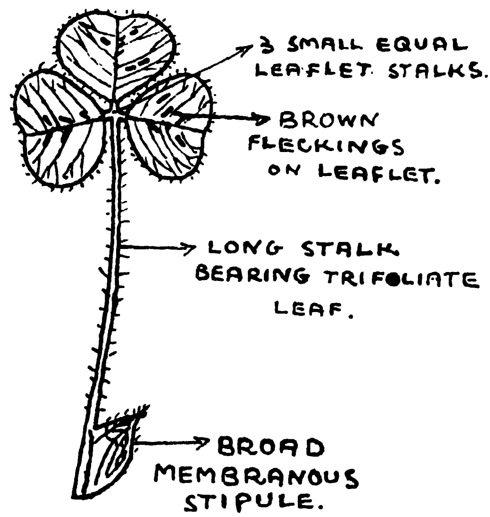

Fig. 22.—Showing Trifoliate Leaf of ordinary late Subterranean Clover (*Trifolium subterraneum*). Only one of the two stipules is shown.

Fig. 23.—Showing lumps or nodules containing *Bacillus radicicola* on the roots of Subterranean Clover.

Legumes are now recognised as necessary constituents of every pasture because they provide the soil with the cheapest form of nitrogenous fertiliser, improve the feeding value of the pasture for stock, and because their feeding value when mature is much higher than grasses at the same stage.

Legumes are the only known family of plants which are able to utilise atmospheric nitrogen. In 1886 Hellriegel and Wilfarth showed that the power of legumes to fix atmospheric nitrogen was due to microscopic organisms or bacteria in the

Fig. 24.—The Life Cycle of *Bacillus radicicola*.
[Taken from *Soil Conditions and Plant Growth* by E. John Russell.]

small lumps or nodules on their roots. (See Fig. 23.) There are various races of this bacteria which is known as *Bacillus radicicola, e.g.*, Lucerne, Subterranean Clover, Lupin, &c., each possessing a different race in their root nodules. Thus the race which forms nodules on Subterranean Clover will not form nodules on Lucerne or the Lupin.

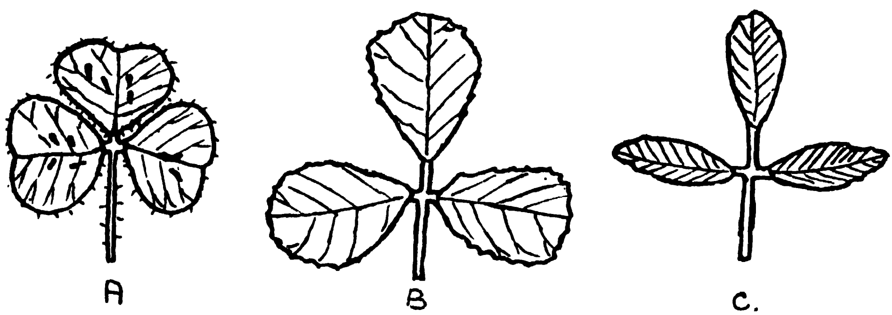

Fig. 25.—A. Showing three equal leaflet stalks, typical of true clover or trifoliums. B. Showing two equal and one longer leaflet stalk, typical of the Medics. C. Showing two equal and one longer leaflet stalk, typical of the Melilots.

The different races of bacteria occur only where their particular host legume is to be found. Without its particular race of bacteria the host legume forms no root nodules, and makes sickly, unproductive growth. At Toora, in Victoria, when lucerne was first grown there, it made very weak growth because of the absence of its race of *Bacillus radicicola*. When soil containing the bacteria was taken from the Werribee lucerne fields and spread over the Toora lucerne it made active productive growth. As the same race of the bacteria occurs in the nodules of both lucerne and the widely spread Burr Clover (Burr Medic), this trouble with lucerne is not likely to occur except perhaps where the soils are very lime-deficient, as in our higher rainfall districts.

With Subterranean Clover there is the possibility that the right race of *Bacillus radicicola* is not present, especially in the poorer sandy soils of the high

rainfall districts, where this clover has never been grown. By sowing poorly threshed seed (*i.e.*, burrs and soil particles present which contain the right race of bacteria) on virgin scrub land this trouble can be avoided.

When the host plant dies the root nodules decay in the soil and the bacteria are liberated. These are able to live for several years in the soil as non-motile cocci (shown as dots in Fig. 24) in the absence of the host legume. When the first true leaves of the young legume are formed, the bacteria move through the soil as motile cocci (black dots with tails in Fig. 24) at the rate of about one inch in twenty-four hours, and penetrate the root hairs of the plant, where they increase in numbers,

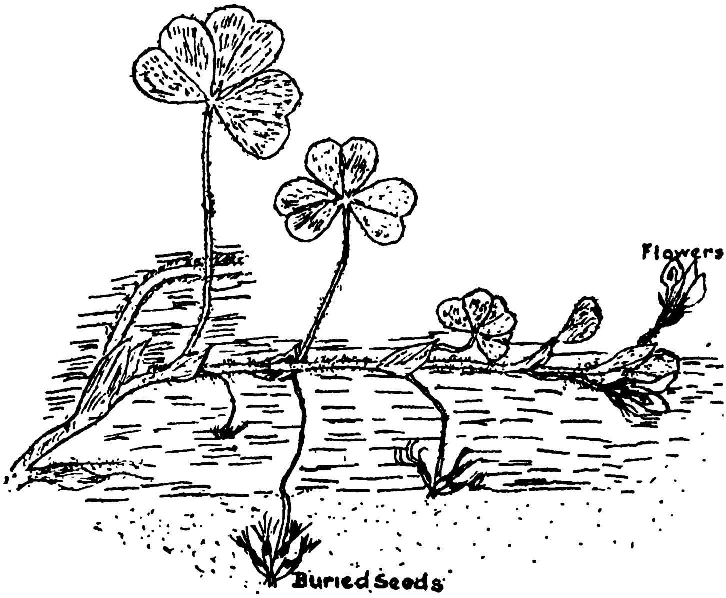

Fig. 26.—Showing the reseeding habit of Subterranean Clover *(Trifolium subterraneum)*.
[From *Some Common Clovers* by A. Morgan, B.Agr.Sc., in *Journal Agric.*, Victoria, March, 1932.]

first as motile and then as non-motile rods (Fig. 24). As a result the cells of the host plant multiply quickly in these regions with the formation of the characteristic nodules. In the nodules the bacteria occur as banded rods (Fig. 24) which break up into non-motile cocci when the nodules decay. The relationship of bacteria and plant is of mutual benefit, because the bacteria extract nitrogen from the soil air, this nitrogen being converted into soluble nitrogenous compounds, which are passed on to the plant. In return, the bacteria receive sugars and other food materials manufactured by the leaves of the plant. From the time they enter the root hair to the time when they are liberated from the decayed root nodules the bacteria pass through a definite life cycle (see Fig. 24).

As Subterranean Clover contains on an average 3½ per cent. nitrogen, 1 ton of dry matter per acre produced during the season would contain nearly 80lbs. of nitrogen. Stock grazing on Subterranean Clover will return at least half of this nitrogen (*i.e.*, 40lbs.) back to the soil. This is equivalent to applying a dressing of over 1½cwts. of sulphate of ammonia to the soil. As about 14 per cent. of the nitrogen of the plant is located in the nodules and roots, the soil is further enriched with nitrogen when these decay.

Thus a pasture legume enriches the soil in nitrogen appreciably, this nitrogen becoming available to non-legumes such as grasses growing in association with or after the legume. The two outstanding plant foods with which pasture grasses and non-legumes have to be supplied are phosphorus and nitrogen. On the other hand,

pasture legumes obtain their own nitrogen, and thus need to be supplied with phosphorus only. Therefore, if legumes and grasses are grown together in a pasture, the productivity can be maintained simply by top-dressing with superphosphate, because the grass obtains its nitrogen from the clover. When a natural pasture is top-dressed with superphosphate, clovers predominate one year and build up the nitrogen of the soil, while the next year annual grasses and weeds will predominate and use up the nitrogen so built up. This occurs because clovers are depressed by a high percentage of nitrogen in the soil and because grasses thrive luxuriantly when there is plenty of nitrogen present. The ideal under these conditions is to have a highly productive perennial grass, such as *Phalaris tuberosa,* growing in association with the clover and using up the nitrogen as it is produced. This leads to what is known as a stable pasture, which can be relied on.

In a pasture, legumes help to make the pasture more nutritious for stock because they are richer in the essential minerals and nitrogen, and in addition have a much higher feeding value at maturity than grasses. The following analyses from Bulletin No. 49 of the C.S.I.R. serve to illustrate this:—

Table Showing Per Cent. Nitrogen, Lime and Phosphorus in the Dry Matter of Wimmera Rye Grass and Subterranean Clover at Various Stages of Growth.

Harvest.	Per Cent. Nitrogen.		Per Cent. Phosphorus as P_2O_5.		Per Cent. of Lime.	
	Wimmera Rye Grass.	Sub. Clover.	Wimmera Rye Grass.	Sub. Clover.	Wimmera Rye Grass.	Sub. Clover.
1st when plants young	4·97	4·74	·87	·71	·86	2·30
2nd	4·49	4·26	·58	·70	·97	2·60
3rd	3·52	3·69	·45	·50	·81	2·17
4th	2·14	2·82	·35	·42	·70	2·22
5th when plants mature	1·60	2·50	·28	·39	·76	2·31
Average per cent. for season	3·3	3·6	·5	·54	·8	2·3

Like the grass family, the sub-family *Papilionatae* of the family *Leguminosae* can be divided into a number of groups or genera.

I.—THE TRUE CLOVER GROUP, OR TRIFOLIUMS.

A true clover always has the three small stalks of the three leaflets equal in size. In this way it can be distinguished easily from a Medic or Melilot (see Fig. 25). In addition the small pea-like flowers are always clustered in a head.

1. SUBTERRANEAN CLOVER *(Trifolium subterraneum).*

As this clover has been described in detail in *Bulletin No.* 240 by *W. J. Spafford, Deputy Director of Agriculture,* the main points only need be considered. It is a hairy prostate annual with heart-shaped leaflets. The stipules are broad and membranous with short hairy points. (See previous Fig. 22.) Subterranean Clover acts like a perennial, because it buries a proportion of the seed crop each year. (See Fig. 26.) Because of this and its relatively large seed—filled with abundant food reserves—the young seedlings are able to develop quickly after germination and provide grazing earlier than other annual clovers. It can also be grazed more heavily than other annual clovers because of its seed-burying and prostate habits.

On the poorer soils of our high rainfall districts (*e.g.*, Hills and South-East) Subterranean Clover with superphosphate is the first step in pasture improvement. After about 8 to 10 years of Subterranean Clover and superphosphate the previously poor soil is converted into a dark friable loam, high in humus and nitrogen.

The appearance of a vigorous growth of annual grasses and weeds is an indication that the fertility of the soil is high enough for the introduction of perennial grasses such as *Phalaris tuberosa*. This is the second step in pasture improvement, and is necessary if a stable balanced pasture is aimed at. An almost pure Subterranean Clover pasture is undesirable, not only because it is unstable, but because it is only suitable for cattle, being unbalanced in nitrogen and mineral content (*e.g.*, it is very rich in lime, as seen by the table given).

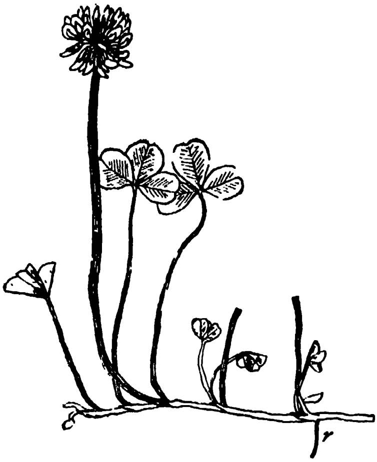

Fig. 27.—Portion of White Clover plant, showing creeping habit of stem and root "r."
[From *Agricultural Botany* by John Percival.]

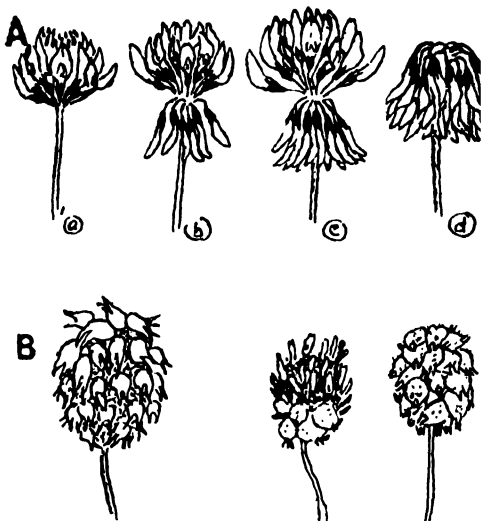

Fig. 28.—A. The various stages in the turning-down of the flowers of the White Clover flower head. B. The characteristic bladdery appearance of a mature Strawberry Clover flower head.
[From *Some Common Clovers* by A. Morgan, B.Agr.Sc., in *Journal Agric.*, Victoria, March, 1932.]

In general, ordinary late Subterranean Clover (Mount Barker strain) needs the more temperate conditions, and will not thrive where the rainfall is less than 22in. Where hot summer conditions appear early the late strains cannot set seed because they are still flowering. However, an early maturing strain (Dwalganup), discovered in Western Australia, is able to set seed where dry weather sets in early. As a result, this Dwalganup strain will be a means of extending the Subterranean Clover zone into the drier cereal belt. It is a good associate clover for Wimmera Rye Grass or *Phalaris tuberosa* in the 17-22in. rainfall belt.

The late strains always have brown fleckings on the leaflets, while the early strain usually has a cream arch on the leaflets.

2. WHITE CLOVER (*Trifolium repens*).

This is a hairless perennial clover with creeping rooting stems. (See Fig. 27.) The light green leaflets are always rounded at the tip, and white markings are often present. The stipules are membranous and transparent, adhere closely to the stem, and have an irregular torn tip. Young White Clover plants can easily be confused with those of Clustered Clover. However, in Clustered Clover the margin of leaflets are toothed, the stipules end in a sharp green point, and the colour of the stipule veins changes from green to purplish.

The flower clusters are white at first, and then become pink when withering. At this stage the flowers commence turning down, beginning at the bottom first. This definitely distinguishes the flower head of White Clover from that of Strawberry Clover, in which the flowers become bladdery and look like a strawberry. (See Fig. 28.)

The perennial habit of White Clover depends upon the new plants formed by the creeping, rooting stem, and the young plants which are continually appearing from the seed formed. Thus the old plants are continually being replaced. It is a highly palatable clover, and can only be grown where there is an abundance of soil moisture in summer, when it makes its maximum growth. Thus it is a good associate clover for Cocksfoot. It can only be grown successfully in favoured spots in the Adelaide Hills, extreme Lower South-East, and under irrigation on the Murray Swamps. The lucerne flea attacks it very readily.

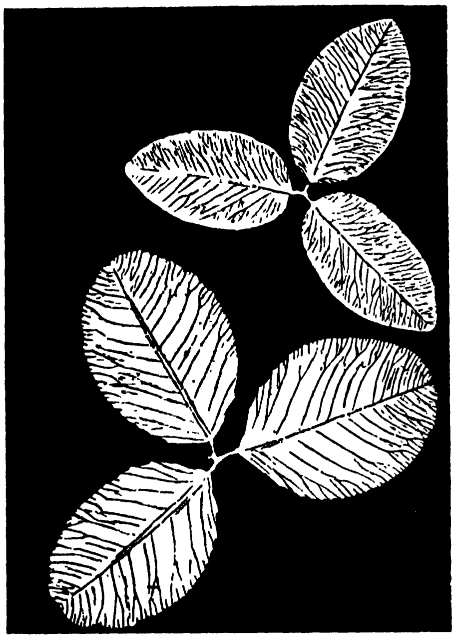

Fig. 29.—Showing the different veining and shapes of the leaves of White Clover (lower) and Strawberry Clover (upper).
[From *Some Common Clovers* by A. Morgan, B.Agr.Sc., in *Journal Agric.*, Victoria, March, 1932.]

There are six types, and of these White Dutch is the worst and New Zealand Wild White the best. Much of the so-called White Dutch sold on the market is really New Zealand White Clover (either certified Wild White or the inferior ordinary White Clover).

3. STRAWBERRY CLOVER *(Trifolium fragiferum).*

This is a perennial clover with creeping, rooting stems. It often possesses some sparse hairs on the leaf stalk. The leaflets are dark green, and often show brown markings. The leaflets are oval in shape, and come to a point at the tip. (See Fig. 29.) The stipules are fleshy with a long point, and possess greenish-purple veins. The flower head has already been mentioned.

It is particularly adapted to marshy localities and rich, swampy, low-lying country, where it makes rapid luxuriant growth. The seed is very difficult to harvest and thresh, with the result that only limited quantities are put on the market at a high price. Thus it is usual to establish Strawberry Clover by planting pieces of the root.

(*To be continued.*)

GRAFTING AS A MEANS OF CHANGING VINE VARIETIES IN A VINIFERA VINEYARD.

[*By* J. L. WILLIAMS, R.D.A., *Viticultural Instructor, Etc., Roseworthy Agricultural College.*]

The writer has from time to time received inquiries concerning the method or methods adapted to the purpose of changing over a variety of vines to a more suitable variety. In view of the apparent necessity of changing over certain red wine varieties, such as "Shiraz," "Mataro," and "Grenache," to more profitable white sorts has suggested that some information on this subject would be acceptable to South Australian vine growers.

It is not, however, suggested that growers having large areas of these red varieties should attempt to graft over the whole of their vineyards to white varieties. It is conceivable that, if this should be commonly adopted, growers would in a few seasons find themselves with an unsaleable surplus of white grapes. At the present time, however, the better white varieties are eagerly sought by the wine makers, whilst on the other hand "Shiraz," "Grenache," and "Mataro" are difficult to quit at a payable price. Further, it may be imagined, if red varieties were grafted over wholesale to white sorts, there would eventually be a shortage of red wine sorts. The most growers should attempt, therefore, is to graft over a small area of red sorts at the one time, say 1½ or 2 acres in the first year, and then only as demand indicates that a further succession of graftings is warranted. The grafting of vines is a long and tedious, but fairly simple operation, providing the grower is prepared to perform it with a sufficient amount of care.

THE EFFECT OF GRAFTING ON THE NUTRITION AND GROWTH OF THE COMPOUND PLANT.

To gain a clear conception of this aspect of grafting it is first of all necessary to consider the life of the ungrafted plant growing under average vineyard conditions.

Dr. A. I. Perold, in his excellent work, "A Treatise on Viticulture," has explained this aspect of the subject in a very lucid manner, and the writer's comments on this point are modelled on Dr. Perold's ideas. The above ground portions of the vine, *i.e.*, stem, arms, canes, and fruit are supplied with their necessary moisture and raw plant food nutrients by the root system of the vine. This root system in return is supplied with elaborated (manufactured) plant food (starch, sugar, protein, &c.) from the leaves. The growth, development, and functions of the root system are governed by the inherent vigour of the variety and by environmental factors, such as moisture, soil texture, plant foods, heat, air, and other factors. So, according to circumstances, the root system has a certain capacity for absorption of moisture and plant foods. This Perold calls the functional capacity of absorption, denoted by "Ca."

Similarly, the aerial portions of the vine have a certain capacity for the utilisation of this same moisture and plant food, turning it into elaborated sap through the agency of its leaves. This capacity for the utilisation of the materials supplied by the roots is termed its functional capacity of consumption "Cv."

An unpruned vine growing under average conditions, in early spring, naturally assumes a condition where "Ca" equals "Cv" (Ca = Cv). Later in the season, when moisture becomes limited, Cv tends to become greater than Ca, and the vine fails to develop its fruit properly, and portion of the plant perishes. The grower prunes his vines with the express object of creating a condition where Ca is greater than Cv, in order that the annual canes may grow strongly in an endeavour to bring back the balance. The size and weight of the bunch bears a close relationship to the size and vigour of the canes on which they are carried, hence by careful pruning the quality of the grape harvest may be suitably regulated.

In drought periods the vine tends to establish a condition where Ca $<$ Cv, with its attendant evils, *i.e.*, weak, brittle canes, fruit but poorly ripened, eyes poorly developed for the next season's crop.

By reasonably heavy pruning the grower gives the root system a little in reserve to tide the vine over a drought period.

In the case of the grafted vine we have a compound structure to consider, and if the functional capacities of the stock variety are represented by Ca and Cv, and those of the scion variety by Ca^1 and Cv^1 respectively, then there are three possibilities, either Ca = Cv^1 or Ca $>$ Cv^1*.
$<$

It is doubtful if there exist two different varieties whose functional capacities are equal, and this becomes more improbable when one realises that the graft union in itself restricts the movement of sap, being more apparent where certain imperfections occur in the knitting (uniting) process. There are then only two cases to be considered, either Ca $>$ Cv^1 or Ca $<$ Cv^1. In certain special circumstances the combination Ca $<$ Cv^1 is made use of, as, for example, the instance of dwarfing stocks being used for certain varieties of fruit trees, where the dwarfing has the effect of permitting early production and more regular cropping. Generally speaking, however, this is a dangerous combination for vines, and the compound plant generally suffers some debility, *i.e.*, it may die suddenly, or gradually over a period; the stock and scion may lack affinity; the vine may not set fruit satisfactorily.

The only reliable combination, therefore, is that where Ca $>$ Cv^1, *i.e.*, we should, if possible, use a scion variety of slightly less vigour than that possessed by the stock variety. Fortunately this is the case in the particular instance under consideration. The three varieties previously mentioned, viz., "Shiraz," "Mataro," and "Grenache," have vigorous root systems, and will give a satisfactory combination with nearly all white grape scion varieties.

GRAFTING AFFINITY.

The term "affinity" refers to the inherent desire on the part of one variety to unite successfully with another variety. All, or almost all, European varieties will unite satisfactorily one with the other. It does not necessarily follow, however, that the compound plant will be a success in the vineyard. The term "affinity" has and is used in a broader sense to embrace the fact of the grafted plant being a success or non-success in a commercial planting, and where the term is used elsewhere in this connection it will be taken to cover this broader application.

* Sign = denotes equals $>$ denotes greater than
$<$ " less than.

Information pertaining to the above aspect of grafting, so far as it applies to combinations of vinifera is very meagre, particularly in the case of wine varieties. The only instances of poor affinity that I can call to mind is that "Muscat Gordo" and "Carbernet" are, generally speaking, unsatisfactory as stocks, and that "Zante Currant," which is usually a good stock, will not succeed with "Shiraz" as the scion, although "Zante Currant" makes a satisfactory combination with "Shiraz" used as the stock.

However, the question of affinity is not of very great moment in the case of vinifera combinations, as most vines used as stocks will permit grafting being conducted below ground, in which case the scion eventually makes its own roots and becomes independent of the stock.

THE INFLUENCE OF EXTERNAL CONDITIONS ON THE FORMATION OF CALLUS AND THE KNITTING PROCESS.

Access to air facilitates the formation of callus, and grafting is not as successful in stiff compact soils as it is in lighter sandy soils, where the graft union is made well below the surface soil.

The temperature of the soil also considerably influences callus formation. The optimum temperature is 30 degrees centigrade (spring temperatures). Callus forms best in almost dry sandy soils (optimum moisture content 15 per cent.). This explains why excess moisture, in the form of heavy rain, very often causes some grafts to fail. For this reason, when grafting in fairly stiff soils in a wet season, it pays to leave the grafting operation until the sap rises in the vines to be treated, or even to wait until growth has started.

In the irrigated soils of the Murray valley grafting can be performed much earlier, in view of the light winter rainfall and light soils, and also for the reason that an irrigation is applied before bud burst, which would interfere with the grafting where it had been applied late.

On the stock, callus forms more readily on a longitudinal section or cleft made on the stem than it does on the traverse section, and with most systems of grafting the operation is performed in a way which takes full advantage of this phenomenon. On the stock or scion, callus forms best on the base of a sloping section, such as is made on the wedge-shaped scion in the "cleft" graft method, and as on the sections on the stock and scion in the "whip tongue" graft method. Also callus forms more readily at the nodes, and least on the internodes, consequently when shaping the scion in the "cleft" graft method the sloping sections should commence at a spot adjoining an eye, as in Fig. 1, and in the "whip tongue" graft similarly as in (*a*) Fig. 3.

METHODS OF GRAFTING.

The grower has the option or choice of two methods, viz., the "cleft" graft method, which necessitates the loss of one full crop, or the "whip tongue" graft in conjunction with layering, which takes advantage of the fact that the change over of varieties can be effected without the loss of the crop.

In this latter instance it will necessitate the use of trellising, in which case, if operating on a bush pruned stock variety, it will be necessary

to trellis the new variety. In fact, wherever grafting is contemplated it is as well to trellis the new variety, as it is very difficult to train satisfactorily grafted vines on the bush principle on account of the very rank and vigorous growth obtained from the graft. Of the two methods, "cleft" grafting is the one more usually adopted by growers, and for which reason this method will be outlined first.

CLEFT GRAFTING.

The method can be applied successfully, both on well established vines and on young vines two or three years old (in the vineyard).

In the first instance the stems of the vines to be grafted will have, according to vigour, a fairly large girth, and in the latter instance the vines will only possess stems, the diameters of which are about ½in. or little more. In each instance the operation is almost identical.

There is a decided dearth of information concerning the success, as a grafted vine, of any two varieties used in a grafting combination, but almost invariably the writer has found that "Shiraz," "Grenache," and "Mataro" will give satisfactory results where any variety of slightly less vigour is used as the scion variety. Where some doubt exists, the difficulty can in most cases be rendered relatively unimportant by effecting the graft union some 4in. to 6in. below normal soil level, whence the scion variety eventually makes its own root system, and after a few years will be quite independent of the stock.

Much, however, depends on the condition of the root system of the stock variety. In some cases, and particularly in stiff soils, the stems of the stocks branch only a few inches below the surface of the soil, in which case grafting cannot be performed other than near the surface, on account of the necessity of having a clean section of the stem for the grafting operation.

In nearly all cases, however, no difficulty will be experienced with the stock varieties previously mentioned.

THE COLLECTION AND TREATMENT OF THE SCIONS.

Medium sized cuttings are best, and these should be cut to a convenient length (say 18in.), using that portion of the canes on which internodes of an even length are to be found. Fruiting canes should be used, and these only from healthy vines of known good cropping capacity. It will be found advisable to mark such vines during the cropping season. The scions should be tied into bundles of not more than 10-15 canes.

A shallow pit should next be prepared, large enough to accommodate the required number of scions, in a light sandy soil. The bundles of scions should be placed in this pit in successive layers, each layer being covered with a few inches of sand and firmed. The last layer of cuttings should be covered with about 6in. of sand to prevent the topmost scions becoming dry. The scions, when lifted for grafting, should be moist, pliable, and show a clear, healthy green colour when cut. Scions which have been stratified in this way will section much cleaner than scions taken direct from the vine, and should grafting be delayed until after bud-burst, these scions will still be in a dormant condition.

SHAPING THE SCION.

Several methods have been advocated for shaping the scion, but the writer has found that scions shaped in the form of a single wedge and possessing two well developed eyes, as in Fig 1, is the most satisfactory, and has the added advantage of simplicity of operation. The two sections

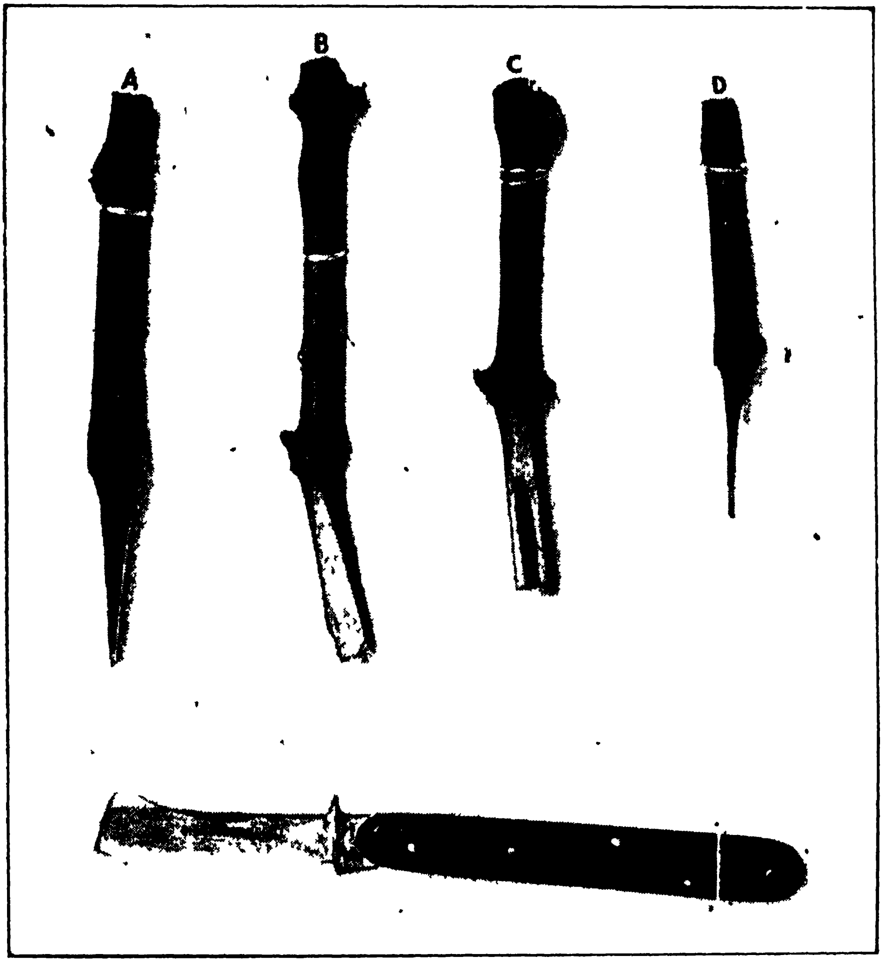

Fig 1—Scions prepared for the Cleft Graft A Showing a side view of the doub'e wedge scion prepared for the cleft graft B and C Showing a general view of the sections of the prepared scion D. Showing a modification of the usual method of preparing the scion, this method is not generally used

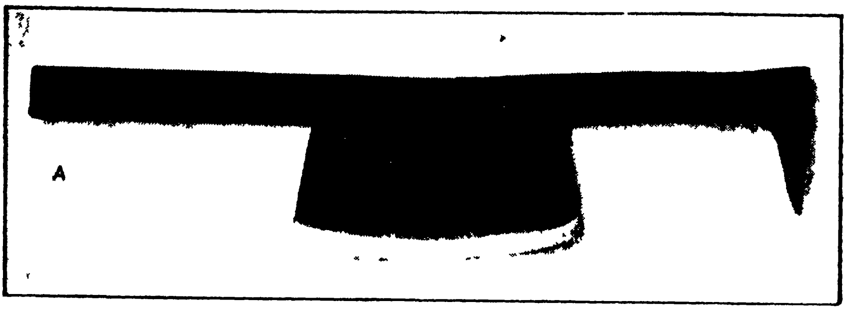
constituting the wedge should be commenced near the eye, to take advantage of the fact that callus forms most readily at this point. For a large stock two scions should be inserted—small vines will accommodate only one.

E

THE PREPARATION OF THE STOCK.

According to circumstances previously referred to, the operation will be performed either below ground or at ground level. In either case the operation is identical. The stem of the vine is severed with a pruning saw on a clean spot on the stem, *i.e.*, avoid making the cut on a knobby portion of the stem, where some difficulty will be experienced in securing a neat fitting of the scion.



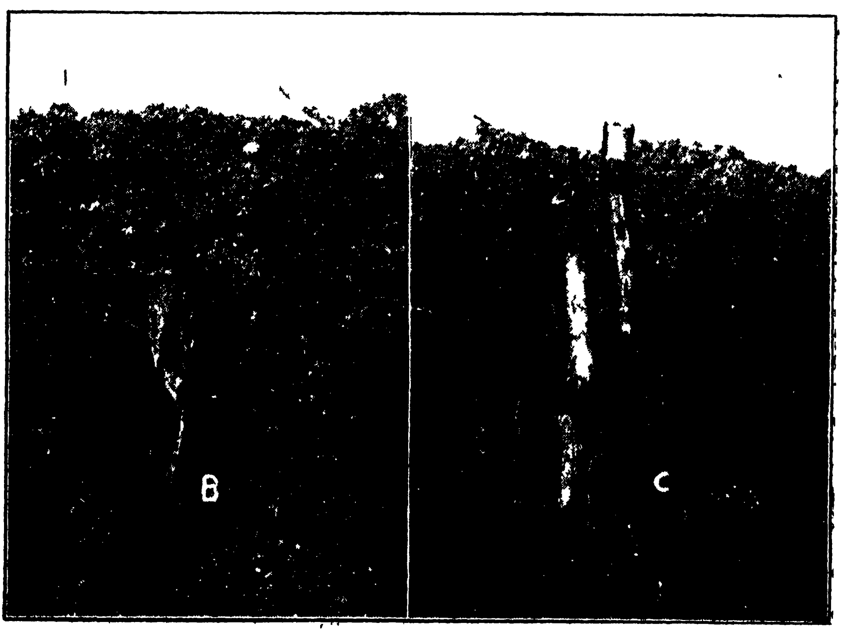


Fig. 2.—Showing method of making the Cleft Graft. A. A grafting chisel made from an old chaffcutter blade and provided with a wedge at one end. B Showing the cleft, which is held open by the aid of a small hardwood wedge. C Showing the two scions in position, with the wedge removed.

The stem is now split down with a grafting chisel (see Fig. 2), with the aid of a wooden mallet. The chisel shown in the figure can be conveniently made from an old chaffcutter blade, and is a very effective implement.

On vines with a stem of small diameter it will be necessary to tie the stock some 2in. below the cross section to prevent an unnecessarily long split, which will result in an ineffective fit.

Stout twine should be used, and should be long enough to be used in binding the stock and scion in position. A simple grafting knot should

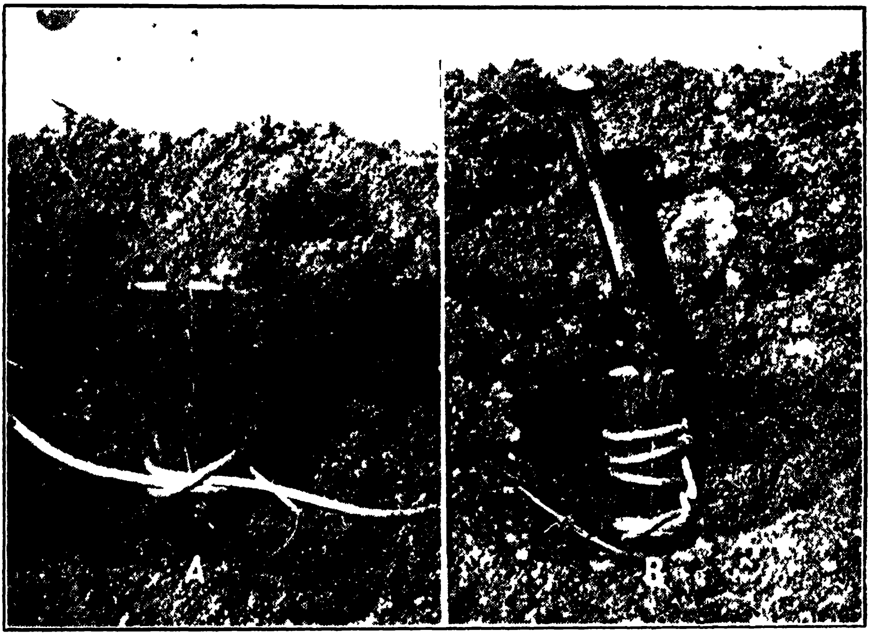

Fig 2a.—The Cleft Graft performed on a Young Vine A Showing the stock which has been prevented from splitting by means of a simple grafting knot (clove hitch) B. Showing the single scion placed in position and firmly bound by the same material as that used for preventing the elongation of the cleft.

be used for this purpose (clove hitch knot). With moderately large stocks it is quite unnecessary to tie the stock or bind the grafted parts together.

INSERTING THE SCIONS.

A small, narrow, hard, wooden wedge should be used for keeping the cleft open whilst the scions are being placed in position. On small vine stocks there is no necessity to wedge the stock open. The main essential in grafting is to ensure the exact juxtaposition of the cambium of stock and scion. The cambium is a thin tissue composed of generative cells (meristem) situated between the inner bark and the woody portion of the stock or scion. It suffices if the scion is inserted flush with the inner bark of the stock.

NOTE.—It is desirable to remove the rough outer bark at the point of union.

The scion or scions having been inserted, the wooden wedge is now removed, when the cleft closes, holding the scions firmly in position.

With small stocks the grafted parts should be firmly bound. The cut surface of the stock is preferably protected with a strip of waxed paper (made by dipping newspaper in moulten grafting wax, 1 part mutton fat, 2 parts beeswax, and 4 parts resin).

The whole of the grafted parts are now covered with a mound of earth several inches above the normal soil level. This mound drains off surplus water and prevents the grafted parts becoming dry. In other words it maintains conditions favourable to the formation of callus and the knitting process. In stiff soils which are liable to exclude air, it is desirable to cover the grafts with sandy soil provided for the purpose.

AFTER ATTENTION TO THE "GRAFTS."

The trellis should be erected before the grafts make very extensive growth. In cases where both scions have knitted successfully (where two scions have been used) one should be severed as soon as it becomes apparent that the other scion has been suitably cemented. One strong cane is allowed to grow to a height, which is regulated according to the method of training adopted and is then pinched to encourage the development of strong lateral shoots to enable the vine's shape to be established in the same season. All other growths are suppressed, unless more are desirable to provide against the possibility of the main cane being damaged.

The necessity of providing the trellis early in the season cannot be too strongly stressed, as any delay in the training or general attention necessary will almost invariably result in the vines being badly shaped.

A point worth stressing in the performance of the "whip tongue" graft is that a modification of the usually accepted method of making the graft is almost essential. The sloping oblique sections made on the stock cane and scion should be much longer than is generally advocated, in order to secure a firm union, and, further, this union must be strongly bound with raffia or similar material. For most purposes for which the "whip tongue" graft is employed these same sections are made fairly short, or abrupt, as in the diagram, in order to obtain a well cemented union. However, the necessary handling to which the grafted parts are subjected is considerable in this operation, and grafting by the adoption of short sections would be little short of impossible to effect with success. By using long sloping sections the stability of the graft union is assured, although the effectiveness of the union is to some extent sacrificed. This does not, however, detract from the value of the graft, because if performed well below normal soil level the scion will eventually make its own roots.

Of the two methods the writer prefers the use of "cleft" grafting on the resulting simple layered vines, on account of its comparative simplicity and effectiveness. Unless the "whip tongue" graft is performed with considerable care the percentage of failures will be fairly high.

AFTER TREATMENT OF THE GRAFTED VINES.

The new vine from the layered graft makes strong growth. One strong cane is retained, and this is pinched to develop laterals for forming the new vine, and these are supported by the trellis.

As soon as the layered vine develops fruiting wood, the parent vine in the following season is treated by removing it at a spot immediately above the offtake of the layer. In no instance must the connection between the roots of the parent vine and the layer be severed until such time as the old stump dies of its own accord. In the above methods of reconstruction it is preferable to collect and use scions from vines of proved fruiting habits.

CHANGING THE VARIETY WITHOUT THE LOSS OF A CROP.

A number of operations have from time to time been devised for the above purpose, but most of these, whilst they are possible, do not appear to have a practicable application.

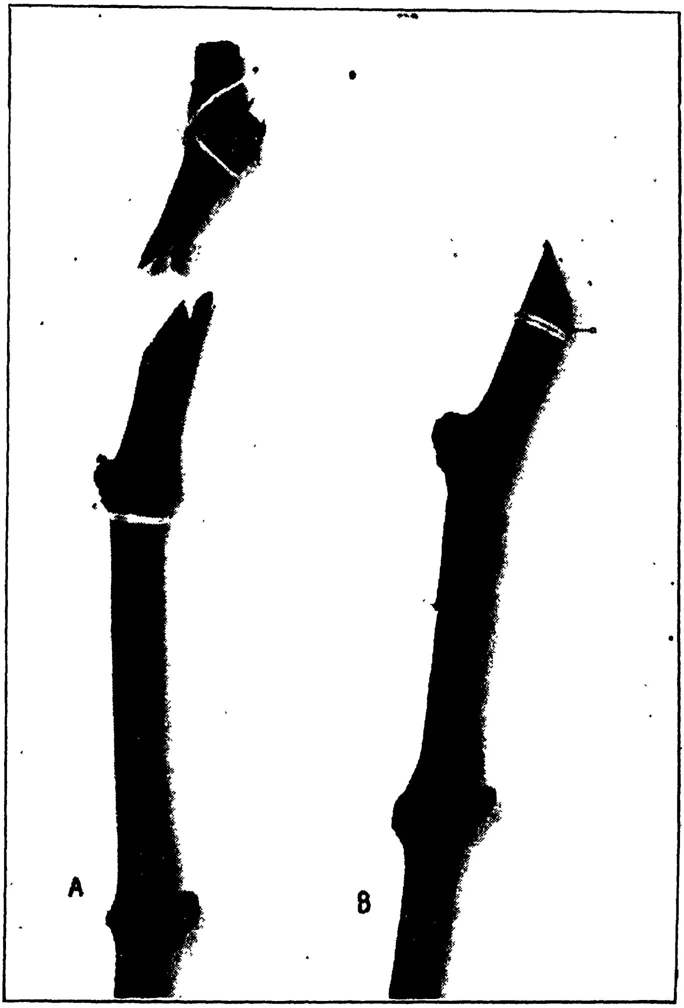

Fig. 3.—Showing details of the method of performing the Whip-tongue Graft. (The normal method of performing the Whip-tongue Graft.) A modification is desirable for the method outlined in these pages, viz., the sloping sections need to be considerably longer. A. The stock. B. The scion.

The method the writer has seen fit to advocate for a variety like "Shiraz" has been employed successfully by Mr. W. Arnst, at Angaston, South Australia, and appears to be a fairly satisfactory and practicable method.

The method would be very difficult to apply successfully on such upright varieties as "Mataro" and "Grenache," which are usually bush trained, but "Shiraz," on the other hand, is well adapted to this system.

The method entails (*a*) the use of the "whip-tongue" graft in conjunction with layering, or (*b*) the establishment of a layered vine at the foot of the parent vine; the vine so formed being in the following season grafted over to the desired variety by means of the "cleft" graft method.

(*a*) In this instance, the dual operation, *i.e.*, grafting and layering may be performed at two seasons, *viz.*, summer (March) and late winter (August).

(*b*) Where the scions fail to knit with the stock, a strong shoot from the layer may be grafted in the following spring by means of the "cleft" graft, or, if the grower prefers, all of the layered vines may be so treated.

Fig 4.—Showing he method of layering and grafting applicable to changing the variety without the loss of a crop. X shows the point at which the grafting operation is performed.

METHOD.

A fairly long and strong cane is taken from the parent vine and to this is "whip-tongue" grafted a portion of the cane of the desired variety. variety.

The accompanying illustrations will be adequate to describe the method of performing the graft, and with a little practice the operator will soon be able to effect the graft easily. It is preferable to effect the graft so that the union occurs as at x in the photograph, because in the case of the graft failing the layer will still make growth in the vegetative season and will provide a vine which may be later grafted by the "cleft" method.

SIMPLE LAYERING AS A MEANS OF RECONSTRUCTING OLD VINIFERA VINEYARDS.

Although this method does not include the grafting operation it is considered desirable to make some mention of the practice here.

A similar method has been adopted successfully by Zante currant growers in the non-irrigated districts of this State.

The "Zante currant" vine, after a period, suffers some considerable disability as the result of continued cincturing, and the vines eventually reach a stage where they become unprofitable.

In the past, this debility has also been partly the result of faulty methods of training and indifferent pruning. In this latter instance the writer refers to vines on which the main arms have been allowed to become permanently twisted around the trellis wires and also to the more or less customary practice of pruning currant vines too lightly, with the consequent poor development of fruiting wood and correspondingly poorly developed fruit. Whichever be the main reason for such debility matters little.

It will suffice to say that such vines usually produce strong water-shoots below the constriction caused by the cincture. One of these water-shoots may be utilised for rehabilitating such vines, with satisfactory results, by removing the top portion of the vines immediately above the water-shoot retained for the formation of the new vine.

This method has been made the subject of an experiment conducted by the Horticultural Branch of the Department of Agriculture, South Australia, at the instigation of Mr. A. V. Lyon, B.Sc., at Clare, Angaston, and South of Adelaide.

An alternative method of reconstruction, and, in the writer's opinion, a better method, is by means of simple layering.

This method of reconstructing currant vines is being compared in a trial with the simpler form of reconstruction, previously referred to, in Mr. G. Wishart's garden, at Angaston, and from accounts promises to be eminently satisfactory. The method is by no means a new one, and is of all methods the soundest, in that the new layered vine eventually makes its own root system, which should conceivably be in a much better condition than the root system of the debilitated parent vine. However, the roots of the parent vine gives to the new vine a very rapid start, necessitating at the most the loss of one season's crop.

A full season's crop need not necessarily be lost in this instance, as a new trellis wire can be supplied for the new vines, in which case the old vines need not be removed until the layered vine has developed fruiting wood, but should this be done the old vines should not be retained for more than one season, as it would obviously restrict the development of the new vines.

However, in most cases it appears sound policy to suffer the loss of one season's crop, as the grower will be recouped for this loss in the increased vigour and cropping of the new vines.

herefore the cows concerned have been credited with only 240 days production.

calving dates had not been supplied to the Herd Book Societies concerned.

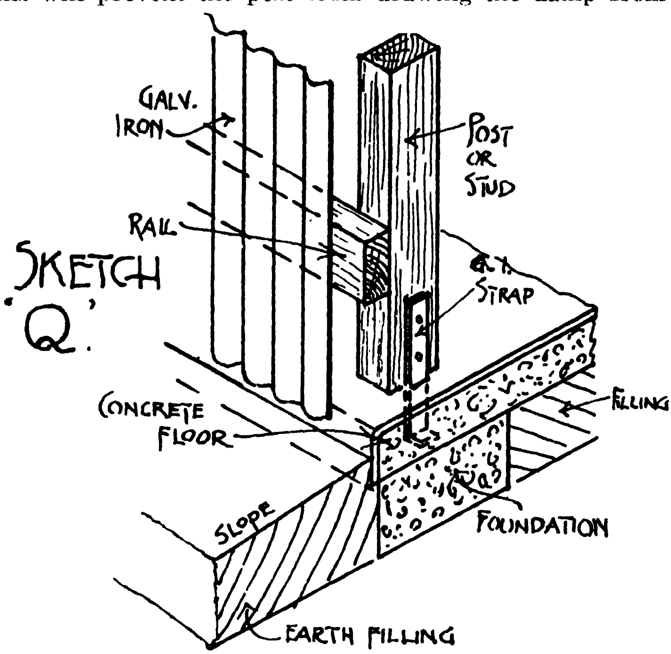
SOME NOTES IN GENERAL ON THE CONSTRUCTION OF BUILDINGS.

[By T. A. MACADAM, Dip. Arch. (Glas.), A.R.A.I.A., Lecturer in Architecture and Building, School of Mines, Adelaide.]

(Continued from July issue.)

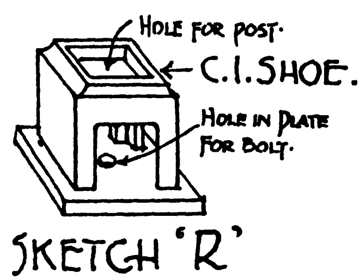
CONCRETE FLOOR.

In some wood and iron buildings it is necessary to have a concrete floor, and this varies the construction shown in the previous portion of this article. In Sketch 'Q' is shown the post or stud resting on the concrete floor and secured to same by a galvanized iron strap. The strap would be let into the concrete when the floor is laid and later secured to the stud or post with two stout screws. The foot of the post should be shod with galvanized iron or a piece of galvanized iron put between the post and the floor. This will prevent the post from drawing the damp from the floor.

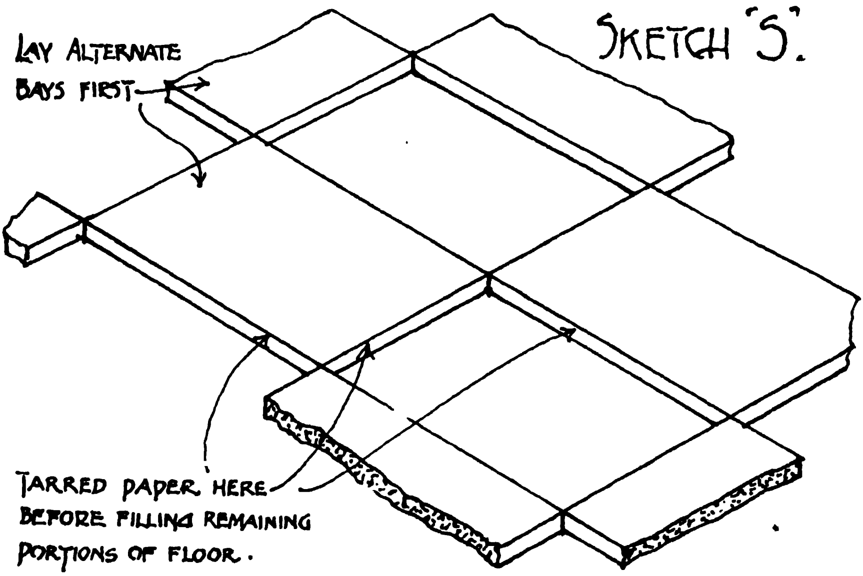


Note the position of the rail in the sketch. This rail should be kept 6in. clear of the floor for the same reason as we protect the foot of the post or studs. The position of a concrete foundation below the posts is indicated, and also the grading of the soil outside the wall to keep the foundation free of surface water.

Another method which is sometimes adopted at the foot of posts resting on concrete floors is to place a cast iron shoe on the floor to keep the post off the floor and in this way the post is kept clear of any damp which may rise from the floor and also prevents white ants attacking the post. The shoes are made from a stock pattern similar to that shown in Sketch 'R.'



While on the subject of concrete floors a reference should be made to the method of laying the floor. A good plan is to divide the area into sections about 6ft. by 3ft. or 5ft. by 4ft. Prepare each alternate section for the concrete by placing the necessary boards at the sides and ends of the sections to be filled. See that these boards are firmly supported in position, and that the soil to be covered by the concrete is firm. The concrete is then mixed and placed in each alternate section. When this



has set the boards can be removed, and in place of the boards put a layer of tarred paper on the exposed edges of the concrete which will be covered when the unfilled sections are filled. The object of the paper is to form a definite joint between the sections of the concrete and permit expansion or contraction to take place without cracking the floor. Tarred paper is suggested, but any other material may be used if it will serve the same purpose. If timber is used it should be removed before the concrete has set.

Any fall required in the floor should be carefully marked on the boards used for keeping the concrete in position. If possible the top of the boards should be set with a fall equal to that which is required on the surface of the floor.

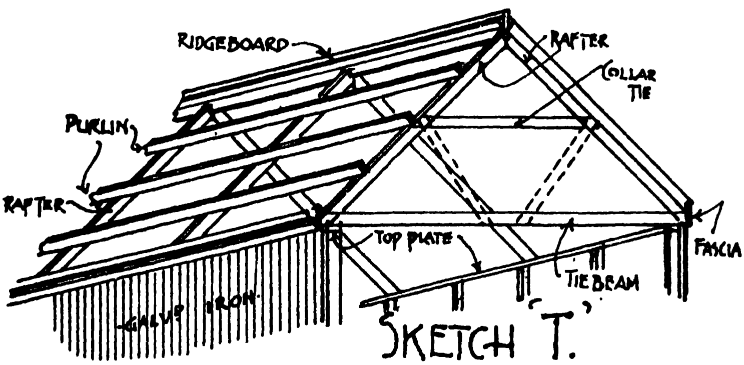
ROOF.

(See notes on roofing in first portion of article in June issue.)

To complete the wood and iron building the roof is considered next. The simplest form of roof is the gable type (see Sketch 'L' in July issue), as there is no special cutting required where the timbers join. This form is constructed with rafters and tie-beam or ceiling joists. At the top of the rafters is placed the ridgeboard, and at the bottom is the top plate

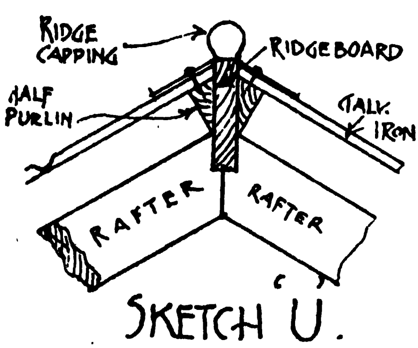
of the walling to which the rafters are nailed and strapped. The ceiling joists or tie-beams are also fixed to the top plate of the walling, and when possible are bolted to the lower end of the rafters.

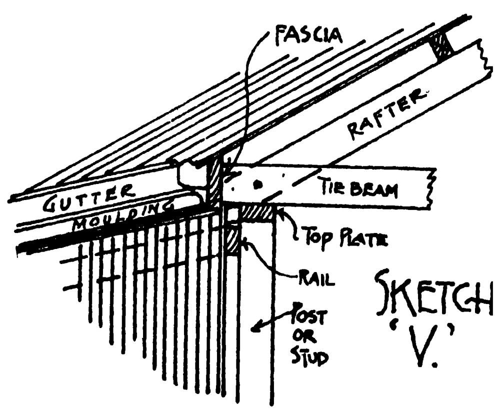
Should a stronger roof be required struts can be added as shown by dotted lines on Sketch 'T.'



The relation of the ridgeboard to the rafters is shown on Sketch 'U.'

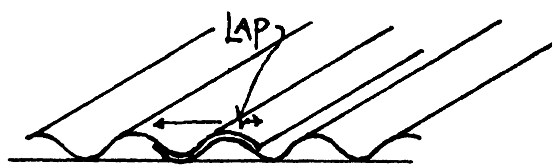
On the top of the rafters are placed the purlins to provide support for the sheets of galvanized iron. The purlins should be spaced at not more than 3ft. centres and fixed in position on the rafters to suit the size of sheets intended for roofing. Secure the purlins to the rafters with 3in.





nails. The next piece of timber to be fixed is the fascia. This is placed at the foot of the rafters in position shown in Sketch 'V' and projecting above the rafter the depth of the purlin. When the galvanized iron sheets are placed on the roof they are secured to the purlins and to the fascia, hence the reason for the fascia having the same relation to the rafter as the purlin.

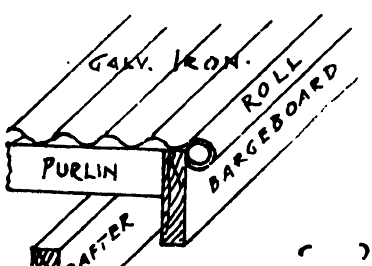
Gutters are next placed in position on the fascias and fixed to them with straps or brackets. Below the gutter is fixed a small moulding for additional support to the gutter. See that the gutter is fixed with a fall to the outlet or down pipe. The sheets of iron are then fixed in position on the roof, overlapping the fascia 1in. When placing the sheets on the roof reverse each alternate sheet and lap over the adjoining sheet on each side one and a half flutes. See Sketch 'W.' At the top and bottom of the sheets the lap should be 6in. A sheet of iron covers approximately 1ft. 11in. wide by 6in. less than its length.



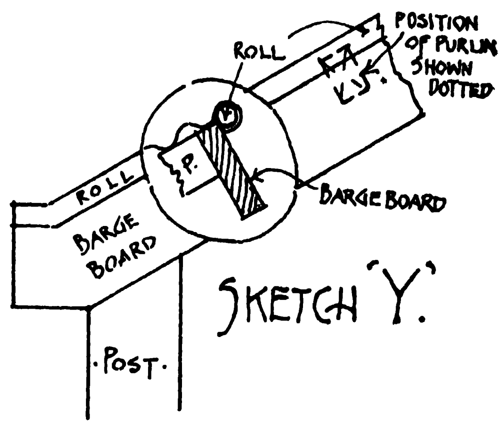
SKETCH 'W.'

SHOWING TWO SHEETS OF IRON LAPPED AT SIDE.

At the gable ends the simplest finish is obtained by placing a fascia or bargeboard on the end of the purlins and running parallel with the rafters



SKETCH 'X'



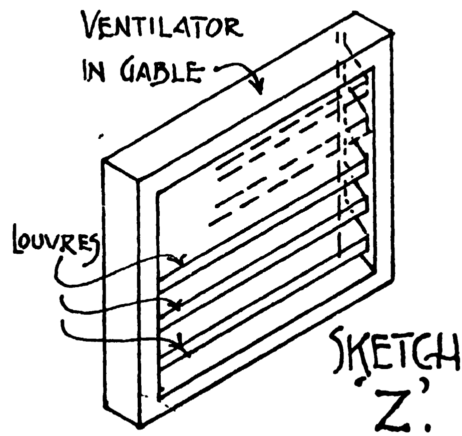
SKETCH 'Y.'

as shown in Sketch 'X.' On the side of the bargeboard fix a 1½in. galvanized iron downpipe at the top of the board and carry the edge of the roofing iron over it as shown in Sketch 'Y.' This will avoid any woodwork being exposed on the roof as mentioned under "Painting," in the June issue.

It will be noticed that the ridgeboard is kept sufficiently high to allow the galvanized iron sheets to butt against it on each side. To enable the galvanized iron sheets to get a fixing at the ridge a purlin is cut diagonally in two, and a half placed on each side of the ridgeboard as shown in Sketch 'U.' When all the sheets are fixed in position a galvanized iron ridge capping is fixed on the top and nailed or screwed to the half purlins.

VENTILATION IN GABLES.

With the gable type of roof, ventilation of the air space under the iron is obtained by placing a louvre vent in each gable. The louvre vent is constructed with galvanized iron louvres placed in a wooden frame which is grooved to receive them. See Sketch 'Z,' which shows the frame with two louvres in position. Note that the louvres are turned down at the bottom or outer edge and up at the top or inner edge. The slope of the louvres should not be less than 45 degrees, and in exposed situations should be 60 degrees. The louvres may be placed 2in. apart and galvanized wire netting should be fixed on the inside of the frame to keep out birds. The louvres should not be longer than 18in. without a centre support. The wood frame could be made out of 3in. x 2in. material with a 3in. x 3in. weathered jarrah sill, and placed between the studs which support the material covering the gable. Put a vent in each gable to ensure through ventilation.



(Concluded.)

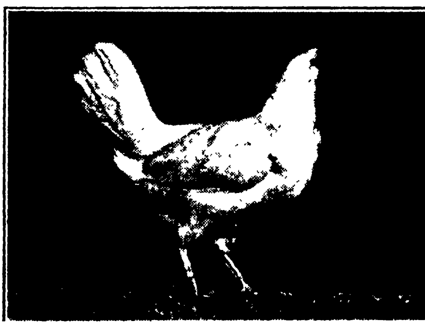
PARAFIELD EGG-LAYING COMPETITIONS, WINTER TEST.

[By C. F. ANDERSON, Poultry Expert.]

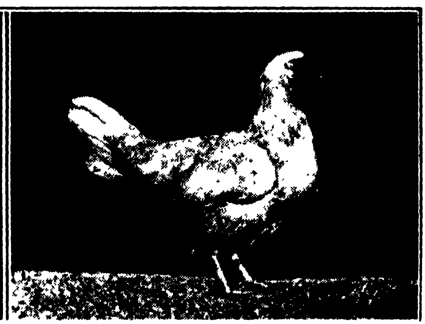
The Egg-laying Competition commenced on April 1st, 1934, and the Winter Test extended until July 31st, 1934, a period of 122 days. The competition is all Single Testing.

There were nine classes in the competition, and the following entries were received :—

SECTION 1.—WET MASH.	
Class 1.—White Leghorns	333
Class 2.—Any other light breed	15
Class 3.—Black Orpingtons	63
Class 4.—Any other heavy breed	30
SECTION 2.—DRY MASH.	
Class 5.—White Leghorns	12
Class 6.—Any other light breed (no entries received)	
Class 7.—Black Orpingtons	9
HOME PROJECT UTILITY SECTION.—WET MASH.	
White Leghorns	19
Black Orpingtons	3
Rhode Island Reds	1
Total birds competing	485



Leading bird, White Leghorn Section, owned by Mr. S. Hill, Bridgewater; score, 86 first-grade eggs.



Leading bird in the Home Project Utility Section, owned by Milton Smith, Salisbury; score, 79 first-grade eggs.

The Home Project Utility Section, in which 23 entries were received, is for scholars who are taking poultry as a home project in the State schools.

The accompanying table of scores gives the number of first grade, second grade, and total number of eggs laid from April 1st to July 31st, the period of the winter test of all birds competing.

Every egg laid throughout the currency of the test is weighed individually, and the following are the conditions governing first grade eggs :—

A first grade egg shall weigh :—

From April 1st to May 31st, a minimum weight of 1¾ozs.

From June 1st to June 30th, a minimum weight of 1⅞ozs.

From July 1st to March 31st, a minimum of 2ozs.

SCORES FROM 1st APRIL, 1934, TO 31st JULY, 1934.

Section 1.—Wet Mash.

Class No. 1.—White Leghorns.

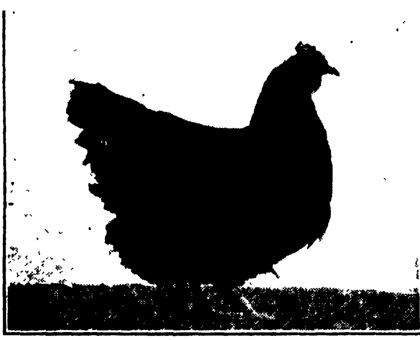
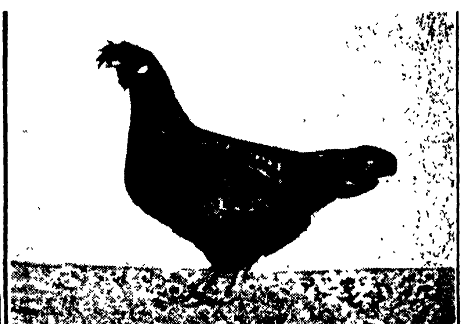
The following table is an interesting one and shows the numbers of first grade, second grade, and total number of eggs laid from April 1st, 1934, to July 31st, 1934, in the various sections :—

Class.	Type of Bird.	Type of Mash.	No. Birds.	First Grade Eggs Laid.	Second Grade Eggs Laid.	Total Eggs Laid.	Percentage First Grade Eggs.
1	White Leghorns.....	Wet Mash	327	14,264	2,925	17,189	82
2	Any other light Breed	Wet Mash	15	477	78	555	85
3	Black Orpingtons ...	Wet Mash	63	3,023	388	3,411	88
4	Any other heavy Breeds	Wet Mash	30	1,473	146	1,619	90
5	White Leghorns.....	Dry Mash	12	535	49	584	91
7	Black Orpingtons ...	Dry Mash	9	370	28	398	92
	Home Project Utility Section	Wet Mash	22	1,022	112	1,134	90

In Class 1 six birds have died, and one bird died in the Home Project Utility Section, April 1st and July 31st.



Leading bird in all sections, a Black Orpington, owned by Mr. F. F. Welford, Colonel Light Gardens; score, 94 first-grade eggs.



Leading bird, Section 2, any Light Breed other than White Leghorn. A Cuckoo Leghorn, owned by Mr. A. Heaysman, Eden Hills; score, 67 first-grade eggs.

The following table shows the leading birds at the end of the Winter Test :—

SECTION 1.—WET MASH.—*First Grade Eggs only.*

Class 1.—White Leghorns.

Singles—	Eggs Laid.	Bird Nos.

Mervyn Steer, Sturt (White Leghorn)	65	443
Eric Pratt, Abattoirs (White Leghorn)	63	441

The results for the winter test are satisfactory, the leading bird being a Black Orpington pullet owned by Mr. F. F. Welford, this bird has laid 94 eggs, all of which were first grade.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.

Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.

Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.

Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.

Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.

Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to July 31st, 1934.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to June 30th, 1934.	No. Eggs Laid Month of July, 1934.	Total Eggs Laid April 1st, 1933, to July 31st, 1934.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

CONFERENCE OF MURRAY LANDS BRANCHES.

The Annual Conference of Branches situated in the Western Murray Lands Division met at Karoonda on July 31st. Delegates were present from the Wynarka, Copeville, Karoonda, Borrika, Coomandook, Lameroo, Yurgo, Nunkeri, and Kulkawirra Branches.

Mr. C. L. Bruce presided and the opening address was delivered by Mr. A. J. A. Koch, who attended on behalf of the Advisory Board. Professor A. J. Perkins, Messrs. W. J. Spafford, R. L. Griffiths, P. H. Suter, C. McKenna, B.V.Sc., H. C. Pritchard, and F. C. Richards represented the Department of Agriculture.

The following papers were read and discussed:—"Methods of Fallowing," G. Sutherland (Copeville); "The Present Day Position of the Farmer," H. Sanders (Nunkeri); "Can Wheat Growing be Made Profitable," E. L. Cowled (Borrika); "Ten Years' Experience of Mallee Farming," R. Elliott (Kulkawirra); "Destruction of Foxes," W. R. Trestrail (Coomandook).

Mr. Koch presented Life Membership Certificates of the Agricultural Bureau to Messrs. G. L. Bonython, E. H. Huxtable, V. V. Brown, L. G. Huxtable, H. S. Green, and J. Waters, of the Borrika Branch.

RESOLUTIONS.

"That the Advisory Board be asked to support the resolution: 'That this Conference ask the Government to allow farmers a free hand in the matter of the proportion of wheat and oats they are allowed to sow.' "

It was decided that the 1935 Conference should be held at Karoonda under the auspices of the Borrika Branch.

"That the Advisory Board of Agriculture be asked to co-operate with farmers generally to refute statements made by several members—as reported in 'Hansard' Nos. 1 and 2 of this session: 'That the Farmers Assistance Act is working admirably and smoothly throughout the State,' and to point out the necessity for drastic amendments to the Act." A committee consisting of Messrs. Aikens, Sutherland, Sanders, Tregilgas, and Coombe made the following suggested alterations to the Farmers Assistance Act, which were subsequently carried by the Conference:—

1. Decentralisation of control of Farmers Assistance.
2. Where a farmer is able to make his own financial arrangements, provision to be made for protection without an application being made under the Farmers Assistance Act.
3. Farmers to have the sole right of deciding what areas of wheat and oats are to be seeded and the respective areas of each.
4. Farmers to have the right to decide quantities of super to be used not exceeding 112lbs. per acre.
5. Farmers to have the right to decide quantities of seed per acre not exceeding 60lbs. of graded seed.
6. Farmers to have the right to sell their own wheat, such wheat to be sold not later than July 31st in each year.
7. The present sustenance allowance is insufficient. It is suggested that the present basis of calculating the allowance be adhered to, not at a rate per week, but at per hour, so that extra hours worked by farmers will be taken into consideration. It is pointed out that the cost of living is much greater in the country than in the city, and that the extra hours worked by farmers entail a greater consumption of food.
8. A greater measure of co-operation by the Farmers Assistance Board with farmers and the Department of Agriculture through the District Agricultural Instructors.
9. It is suggested that no restrictions be placed on farmers when arranging their seeding programme with a view to providing reserves of fodder, and that there be no compulsion to force farmers to sell reasonable reserves of fodder.
10. The Debt Adjustment sections of the Farmers Assistance Act to be extended and put in operation immediately.
11. Reduction of interest on hire purchase agreements.

Conference resolved that a petition requesting the Government to make a reduction in the valuation of land, which was drawn up by Mr. Jones, of the Wynarka Branch, should, on being compiled, be forwarded to the Commissioner of Crown Lands.

The Evening Session was occupied with an address, "Ailments of Farm Stock," by Mr. O. McKenna, of the Stock and Brands Department.

A Special Session was held for Women, at which Miss E. Campbell, of the Education Department, delivered an address, "The Uses of Hessian in the Home."

UPPER NORTH BRANCHES IN CONFERENCE.

With an excellent attendance of delegates from the Yandiah, Wilmington, Morchard, Willowie, Wepowie, Richman's Creek, Murraytown, and Eurelia Branches, the Upper North Bureau Conference was held at Wilmington on July 18th. Mr. F. Coleman (Member, Advisory Board of Agriculture), Professor A. J. Perkins (Director of Agriculture), Messrs. W. J. Spafford (Deputy Director of Agriculture), H. B. Barlow (Chief Dairy Instructor), C. McKenna, B.V.Sc., M.R.C.V.S. (Veterinary Officer), C. A. Goddard (School of Mines), E. L. Orchard, J. B. Harris, J. O. Hatter (District Instructors), H. C. Pritchard (General Secretary), and F. C. Richards (Assistant Secretary, Agricultural Bureau) attended on behalf of the Department of Agriculture.

Mr. M. Christopherson (Chairman of the Wilmington Branch) presided, and the opening address was delivered by Mr. F. Coleman.

The following papers were read and aroused keen discussions:—"Aberdeen Angus Cattle", by Mr. C. Cole (Wilmington); "Factors Influencing the Fixing of Prices", Mr. O. Knauerhause (Wepowie); "Farming as a Business Proposition", Mr. S. McCallum (Willowie); "Observance of Practical Farming", Mr. J. G. Schuppan (Wilmington); "Improving the Standard Sample of South Australian Wheat", Mr. E. H. Hampel (Wilmington); "Handling and Care of a Small Flock of Sheep," Mr. G. Fraser (Wilmington). Officers of the Department took part in the discussions and replied to questions.

Delegates at Upper North Conference, Wilmington, July 18th.

Mr. F. Coleman presented the trophies to the following successful competitors in the Far North Crop Competition:—First prize, Mr. E. H. Hampel, of Wilmington; second prize, Mr. R. C. Llewellyn, of Morchard; and third prize, Mr. E. A. Schulz, of Wilmington.

The following resolutions were carried:—"That the 1935 Conference be held at Pekina under the auspices of the Wepowie Branch." "That owing to the break of gauge—stock having to be yarded at the station two nights previous to market—we request the Government to allow stockowners 120 miles or over from the Abattoirs to co-operate in transporting livestock to the Abattoirs market by primary producers' trucks." "That the Government rescind the present butterfat test system and revert to the commercial value system." "That this Conference strongly recommends that the Government be requested to continue the holding of the Annual Bureau Congress under the same conditions as have obtained in the past."

Mr. C. McKenna addressed the Conference on "Common Ailments of Farm Stock."

THE TREATMENT OF WOUNDS IN FARM STOCK.

[An Address Broadcast through 5CL, Adelaide, by MR. A. H. ROBIN, B.V.Sc., *Veterinary Officer, Stock and Brands Department.]*

No matter how careful an owner may be in safeguarding his stock, accidents will happen to them—a horse will pick up a nail in his foot, get hung up in a barbed wire fence, or get kicked by another horse, or, again, a cow will get horned by another one, and so on.

When such things happen they must, of course, just be met and steps taken to effect the necessary repairs. In country districts, particularly, the job of doing this will as a rule devolve upon the stockowner himself, owing to there being no trained veterinarian available to do the "doctoring" for him, and he ought, therefore, to have a knowledge of the general principles of wound treatment so as to be able to handle satisfactorily each and every case as it arises.

The first thing to be done in dealing with any wound is to control the bleeding. Where this is slight, it will usually stop quickly of its own accord. But when it is more severe, steps have to be taken to hasten its cessation to avoid any undue loss of blood. Excepting where one or more large blood vessels have been cut or torn, this can generally be effected by plugging the wound tightly with cotton wool, or by liberally dusting on some styptic agent, such as powdered alum, flour, or finely ground tea leaves, or by repeated applications of very hot water. If the wound is on a limb, a thick pad of cotton wool, either by itself or impregnated with any of the agents I have just mentioned could be applied over the wound and held in position by tight bandages, which should then be left undisturbed for 24-36 hours, so that when they are taken off for further treatment of the wound, the bleeding will not be likely to recur.

If, on account of one or more large blood vessels being cut, these measures are ineffective, and there is danger of the animal bleeding to death, an attempt should be made to pick up and tie a ligature round the ends of the bleeding vessels. Failing this, as a last resort, the end of a poker could be heated to a dull red heat and applied lightly to them a few times when success will result. This treatment may somewhat retard ultimate healing of the wound, but there need be no fear of bad results ensuing from it.

The next step is to cleanse the wound, and this should be done by bathing or irrigating it with clean warm water to which has been added a little lysol or other antiseptic. If the wound is a clean cut one, it is best to use as little solution as possible, but if it is a badly torn one, then plenty of solution should be used to wash it thoroughly and remove every piece of dirt, grit, &c.

Simple cuts and wounds will, as a rule after this, require no further treatment beyond dusting occasionally with boracic acid or other antiseptic dusting powder.

If the wound is, however, a large gaping one it will be necessary to bring its edges together by stitching, so as to get rapid healing with a minimum of scarring.

If proper suturing appliances are not available, a small bag needle and a fairly stout piece of clean string will answer the purpose quite well, both needle and string, of course, being soaked in an antiseptic solution before use.

Before commencing the stitching, the hair and any shredded flesh at the edges of the wound should be trimmed off with scissors, though torn pieces of skin are better left until it is certain that they are dead before removing them.

In carrying out the stitching, a series of separate stitches should be put in, tying each with its own knot so that if later one or two of them should break away, the whole wound will not gape. In putting the stitches in, give them plenty of hold; it does not hurt the animal any more to put them in ¼in. from the edges of the wound than it does to put them in nearer, and there is then less chance of their subsequently tearing out. Each stitch should be tied as it is put in, gradually bringing the edges of the wound together as closely and evenly as possible, and about ¾in. should be allowed between the stitches.

If a needle is not available for stitching to be done in this way, ordinary pins could be used in the emergency by sticking them transversely through the two edges of the wound, bringing these together and making fast with piece of string tied in a figure of 8 round the projecting ends of the pins.

Most wounds that are bad enough to require stitching will, in the course of a day or two start to discharge matter, and one or two of the lower stitches may then have to be removed to provide drainage for this. Subsequently the wound should be gently irrigated daily with weak antiseptic solution till the discharge ceases, when these watery dressings should be discontinued and dry dressings only used until healing is completed.

Any growth of "proud flesh" that that forms in the wound during its healing should be controlled by the judicious application from time to time, as is found necessary, of a little bluestone, but care should be

taken that this dressing is not allowed to come into contact with the new skin growing over from the edges of the wound, for the bluestone would eat this away, just as it does the proud flesh, and the healing over of the wound would be retarded. If wounds are situated on the limbs anywhere below the knee or hock proud flesh is extremely likely to appear in them, and the most effective way to check its growth is to keep the wounds regularly bandaged in between dressings till they are completely healed over. Otherwise a bad scar will remain to depreciate the animal's market value.

Contused or badly bruised wounds require a special treatment in their early stages. With them, hot antiseptic fomentations should be applied frequently in order to allay inflammation and prevent, as far as possible, death and sloughing of the injured tissues. After the acute inflammation has subsided, the subsequent treatment of them as may be necessary follows on the lines I have detailed for clean cut or lacerated wounds.

Punctured wounds, such as are made by pointed stakes, nails, pellets of shot, &c., should be carefully explored with a sterile probe to determine their depth and direction, and whether there is any foreign body present in their depths. This probing should be carried out very carefully, especially if the wound is in the vicinity of a joint.

If a foreign body is present, it must be removed before healing of the wound will take place, and to effect its removal it may be necessary to enlarge the surface opening of the wound with a knife or pair of scissors, so that it may be reached and got out. Even where there is no foreign body present it may be taken as a broad general rule in dealing with punctured wounds, that enlarging their openings is good, sound practice, as it enables their depths to be more readily and more thoroughly cleansed, and it permits of better drainage for the discharge of matter that is certain to follow in a day or so. Otherwise this type of wound will often close over on the surface, imprisoning the pus, which, gradually increasing in amount and having no outlet, will start to burrow in the adjacent tissues and so complicate matters.

If the direction of a punctured wound be such that it cannot be effectively drained through its surface opening, another artificial opening for drainage should be made through the skin at some suitable spot lower down, and this connected up with the bottom of the wound. Regular daily irrigations with an antiseptic solution must, of course, again be practised so long as the wound discharges.

In the case of punctured wounds in the sole of the foot—and these are very common accidents with horses—a little turpentine run into them immediately they occur will often prevent any further trouble from developing with them. If, however, a day or two after such a wound has been received, the animal becomes very lame, the puncture must be well opened up with a blacksmith's foot knife so that matter that has formed there may escape and any foreign body, such as a nail, &c., be located and removed. The foot should then be immersed in a bucket of hot antiseptic solution for 20 to 30 minutes, or even longer if possible, after which it should be taken out of the bath, dried without being allowed to touch the ground, a little tincture iodine run into the wound, and the whole foot finally encased in a piece of sacking to keep it free from soilage by contact with the ground. This method of dressing

should be repeated once or twice daily till the discharge ceases and lameness disappears, after which the wound in the sole should be filled with Stockholm tar and plugged with a pledget of tow or cotton wool, or a leather sole can be fitted under the shoe to protect the wound until it has healed over.

In conclusion, in all cases of severe wounding the animal should be given a dose of physic and be kept on light diet.

Precautions should also be taken to protect wounds against attack by flies, and if this cannot be obtained by bandaging, or otherwise covering them over, so that they remain exposed, a very satisfactory application which can be used to smear round the edges of them to keep the flies away is a mixture of 1 pint of oil of tar and 1gall. of crank case oil.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, July 25th, 1934, there being present Messrs. A. J. Cooke (Chairman), A. L. McEwin, H. N. Wicks, P. J. Baily, F. Coleman, J. B. Murdoch, A. J. A. Koch, Professor A. J. Perkins, Professor A. E. V. Richardson, and H. C. Pritchard (Secretary).

Resignation.—The Secretary read correspondence from Mr. A. J. Cooke, conveying to the honourable the Minister his regret that on account of pressure of work and greater business responsibilities, he was compelled to resign his seat on the Board as from the date of the August meeting. At the special request of members of the Board, Mr. Cooke consented to act as Chairman until the next meeting.

New Branch.—Approval was given to the formation of a new Branch at Echunga, with the following persons as foundation members:—Messrs. E. Dennis, A. Hauber, C. W. Lampard, E. D. Webb, T. Grisswood, A. Stevens, F. H. Wickham, L. H. Walters, J. E. Assender, D. J. Foxwell, T. E. Hincks, S. Lambert, F. A. Merrit, C. McDonald, W. H. L. Norman, A. T. Rodger, W. Restall, L. W. Sando, G. Symes, and R. W. C. Swincer.

Life Membership.—The following persons were approved as life members of the Agricultural Bureau:—J. E. Quick (Yandnarie), S. H. Pearce, J. Saunders, Geo. Tucker (Strathalbyn), A. K. Ashby (Blackwood), A. J. Bartlett (Willowie), L. A. Orwell, E. F. Davidson (Lameroo), S. Sanders (Moorook), S. H. Goldsworthy, A. D. Matheson, M. McBain, J. M. Yelland, W. S. Yelland (Milang).

New Members.—The following names were added to the rolls of existing Branches:—Frances—J. McDonald; Berri—J. T. Robertson, W. H. Chilton; Laura Bay—Joel Lowe, Brian Stapleton; Belalie Womens—Mrs. H. Bailey, Mrs. K. Symonds; Snowtown—C. M. Dolling; Snowtown Womens—Mrs. G. Jamieson, Sister Kenihan, Sister Mudge, Mrs. F. A. Pritchard, Mrs. E. Pridham, Miss M. Slattery, Mrs. B. Thomas, Mrs. A. V. Walkington, Mrs. H. A. Woodhouse, Mrs. E. S. Allen, Mrs. C. Atkinson, Mrs. J. B. Dolling, Mrs. E. Hupfield, Mrs. N. B. Hawkins, Mrs. G. Herbert, Mrs. L. V. Hancock, Mrs. T. Jenkins, Mrs. A. J. Jensen, Mrs. J. E. Pridham, Mrs. J. Slattery, Miss S. Wittwer; Apilla—L. B. Klemm; Clare Womens—Mrs. J. T. Miller, Miss V. Gillen; Renmark—J. N. Price, J. Showell, W. Appleby, T. M. Appleby; Angaston—Rae. Robinson; Kapinnie—T. R. Reynolds, K. Lawrence; Roberts and Verran—E. Ramsey, T. Masters, W. Standing; Taplan Womens—Mrs. R. Clark; Yadnarie—K. R. Kobelt; Black Rock—W. Crosby, F. Benschke; Yundi—J. A. Gryst; Yadnarie—H. W. Pfitzner, R. M. Spriggs.

No. of new members, 49; present No. of members, 7,772; present No. of Branches, 336.

Several items were discussed in Committee.

DAIRY AND FARM PRODUCE MARKETS.

Messrs. A. W. SANDFORD & Co., LIMITED, reported on August 1st, 1934.

BUTTER.—Conditions in connection with the dairying industry so far this season are very parlous. No finality has yet been reached in regard to an equalisation plan, and those engaged in the industry are awaiting, with interest, the outcome of the proposed Act to stabilize prices. Production generally is very backward indeed and the record drought conditions are making it very difficult for the men on the land. Hand-feeding has been in vogue for many months, but feed for the stock is now getting very short on most farms, and with the pastures so backward, butter production is only about 50 per cent. of what it was at the corresponding period last year. Fortunately the London market has shown a little improvement recently, and at date choicest Australian was selling at 73s. per cwt. Local rates are:—Choicest creamery fresh butter in bulk, 1s. 0¼d. per lb.; prints and delivery extra (these prices are subject to stabilization levies); store and collectors lots, 6½d. to 7½d. per lb. at store door, according to quality.

CHEESE.—The South-Eastern factories are experiencing better conditions than in the north, and supplies are now steadily improving. Fortunately they have had more rainfall in these districts and the pastures are in fairly good growth. Exporting of cheese will commence, and this ought to relieve the market of the increasing stocks. Local and interstate sales have been slow for several weeks past, but will, no doubt,

improve when holders' stocks have been consumed. Present prices are:—Large and medium, 8½d. to 8¾d. per lb.; loaf, 8¾d. to 9¼d. per lb.; semi-matured and matured, 8¾d. to 9½d. per lb.

EGGS.—The production of eggs in country districts is backward, due, no doubt, to the lack of greenfeed. There was, however, a seasonal increase during the last few weeks, but it does not seem likely that the arrears will be made up. Exporting is now in full swing. Rates at present are:—Ordinary country eggs, fair average quality, 9d. per dozen; export quality, 1⅞ozs. and over, up to 10d. per dozen.

BACON.—Sales of bacon continued well up to the average, but buyers operated more particularly for middle cuts and boneless rolls. Hams are still slow of sale, which is usual during the colder months of the year. Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; rolls, 8d. to 8½d.; hams, 11d. to 11½d.; cooked, 1s. 2d. to 1s. 2½d. per lb.; lard prints, 6½d. per lb.

ALMONDS.—Are selling readily and better supplies are reaching the open markets. Values are steady. Softshells and Brandis, 8½d. to 9d. per lb.; hardshells, 5½d. per lb.; kernels, 1s. 11d. to 2s. per lb.

HONEY.—Sales so far this season have been disappointing, although the production has been less than last year. The carry over of stocks was more than sufficient for all needs, and considerable stocks are still on hand. Rates are:—Prime quality clear extracted, 3d. to 3½d. per lb.; lower grades, 2d. to 2½d. per lb.

BEESWAX.—Sold freely from week to week and values are steady; 1s. 4d. to 1s. 4½d. per lb., according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Thursday, and Friday, and our sale rooms are the best equipped in the State. Supplies have improved during the last week or two but with retail distributors short of stocks in cold stores, a good demand was experienced at each of the sales. We advise consigning. Crates loaned free on application. The following are the prices realised:—Prime roosters, 3s. 7d. to 4s. 8d.; nice conditioned cockerels, 3s. to 3s. 6d.; fair conditioned cockerels, 2s. 4d. to 2s. 11d.; chickens, lower; heavyweight hens, 2s. 8d. to 3s. 4d.; medium hens, 2s. to 2s. 6d.; light hens, 1s. 8d. to 1s. 11d.; couple of pens of weedy sorts, lower; prime young Muscovy drakes, 3s. 6d. to 4s. 6d.; young Muscovy ducks, 2s. 2d. to 2s. 11d.; ordinary ducks, 1s. 6d. to 2s. 3d.; ducklings, lower; geese, 2s. 8d. to 3s. 7d.; goslings lower; turkeys, good to prime condition, 8d. to 11d. per lb. live weight; turkeys, fair condition, 6½d. to 7½d. per lb. live weight; turkeys, poor and crooked-breasted, lower; pigeons, 4½d. to 5d. each.

POTATOES.—New season's, 10s. per cwt.

ONIONS.—Brown Spanish, 9s. 6d. per cwt.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of July, 1934, also the average precipitation for July, and the average annual rainfall.

INDEX TO BUREAU REPORTS—*continued.*

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying.	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SOUTH-EASTERN DISTRICT.

ALLANDALE EAST.

June 22nd.—Attendance, 14.

THE AGRICULTURAL BUREAU.—The Hon. Secretary (Mr. J. Laslett) read the following paper:—"It is just forty-seven years ago since the late Mr. Albert Molineux, when giving evidence before a 'Select Committee on Vegetable Products,' suggested the establishment of an Agricultural Bureau. In 1888 the Government adopted his suggestion, and at the end of that year there were established in the State 5 Branches with a membership of 53. From this humble beginning the Agricultural Bureau has grown to over 300 Branches with a membership of over 8,000. The primary object of the early Bureau was to collect and publish by means of the Press, information of every kind calculated to prove beneficial to the colonists engaged in agricultural, horticultural, pastoral, and other pursuits connected with the cultivation of the soil. This is still the main object of the Advisory Board of Agriculture, which controls the many Branches of the Agricultural Bureau throughout the State, but to-day we have a Department of Agriculture, with officers possessing special technical knowledge of certain branches of agriculture, besides experimental farms and similar institutions for research and investigation—advantages which the early Agricultural Bureau did not possess. The Bureau does not now solely depend on the Press for publication of material affecting its members. The *Journal of Agriculture* is issued monthly by the Department of Agriculture. It is the medium by which the Department gives publicity to the work done by its various Branches, and it is also the official organ of the Agricultural Bureau. At the meetings of local Branches members not only hear papers by their own members, but they also benefit by hearing lectures and addresses on agricultural subjects by men who have made a thorough study of their work, and who are at all times ready to assist the man on the land. Treatment for stock diseases, identification of weeds, &c., can be referred to authorities on these matters, and all the Bureau member has to do is to await the reply and act upon it. At District Conferences which are held at various centres throughout the State, and at the Annual Congress in Adelaide, representatives of Bureaus have an opportunity of hearing officers of the Department speak on selected subjects. Resolutions which had their origin in the small local Branch may be brought per medium of the Annual Congress before the proper

authorities, and matters affecting the whole State discussed. Members thus have, in the Advisory Board, a powerful agent working in their interests. Local Branches have been freely criticised. It has been said that Branch members do not practise what they preach. Perhaps this statement is true, but very often it is because members lack finance that their ideas are not carried out on the lines suggested. But papers given by members of one Branch are not intended for the benefit of that Branch only, and ideas brought forward may assist primary producers in other districts miles away from where the ideas originated. Apart from the social aspect, the effect of a few members meeting monthly together to discuss their problems and striving to find a solution for them must surely have an educational value. Let us then, as members, strive to do our part to ensure the smooth working of the Branch, by being punctual and exhibiting a keenness in the discussions brought forward, by contributing to the Agenda when our turn comes, by enlisting and encouraging new members, and thus ensuring to the coming generation the value of the Agricultural Bureau.''

NELSHABY AGRICULTURAL BUREAU.

ANNUAL SEED WHEAT COMPETITION, 1934.

Judged by E. L. Orchard, R.D.A. (District Agricultural Instructor.)

The conduct of this Competition annually by the Nelshaby Branch of the Agricultural Bureau demonstrates in a practical manner the endeavour of members to encourage the sowing of a first class sample of seed throughout their immediate neighbourhood. This worthwhile phase of the work of the Branch has been carried on for a number of seasons, with definite benefit to the quality of grain reaped from the wheat fields of the district, and although there may be still room for improvement, particularly in the direction of the elimination of barley, the results indicate the wisdom of the committee of management in continuing the contests from year to year.

Competitions of this nature may not attract the attention of a number of growers in any one year, but the gradual leavening process which undoubtedly goes on, though slowly, nevertheless surely permeates the careless ''near enough'' attitude too often met with. Wheat-growing at the moment is at somewhat of a discount, due to the run of abnormally low prices constituting a value below that of the cost of production. However, the hope, not altogether without foundation, that prices cannot always remain at the present extremely low level prompts us to explore every available avenue likely to lead to increased yields to assist in making up the previous leeway, and to succeed in this laudable objective, one of the first essentials surely must be the sowing of the

best seed obtainable. Instances of the increased value accruing from the use of properly graded seed are so numerous as to destroy any lingering doubt regarding the results in pounds, shillings, and pence, whilst the sowing of varieties without an admixture of heads of other kinds brings a further reward as being true to type. Admitting the truth of the contention, that our present methods of marketing do not offer much inducement toward the complete elimination of other objectionable features from the shipments of wheat sent overseas, nevertheless the standing of an owner, together with his property, are enhanced by success in a competition of this kind, and has its reflection in many ways in local business dealings, even to the extent of a radiation of some of the warming rays of praise over the boundary fences.

This Competition was divided into two classes, a trophy being offered for the best collection of two varieties, and another for the champion variety of seed wheat, taken as the individual sample receiving the highest total of points. Samples of 2lbs. each in weight were tabled for judging, procured from five-bag quantities on the farms. In the class for two varieties, No. 3 entry made by Mr. F. Jose gained the highest number of points, the wheats presented being Nabawa and Quality, and their scoring 85.75 points and 94 points respectively, a total of 179.75 points. The sample of Quality, which did so much in winning the previous class for Mr. Jose, proved the champion variety, with its allocation of a total of 94 points.

No.	Name.	Variety.	a. 25	b. 15	c. 15	d. 20	e. 15	f. 10	Total Class 2. 100	Total Class 1. 200
1	T. Davies	Nabawa	19·75	12	14	17	12	8	82·75	169·75
		Currawa	21·5	13	13	19	13·5	7	87·00	
2	E. T. Franks	Currawa	22·5	12·5	14	20	14	6	89·00	178·25
		Nabawa	22·25	13	14	18	14	8	89·25	
3	F. Jose	Nabawa	19·75	12	14	20	13	7	85·75	179·75
		Quality	24·50	12	13	20	14·5	10	94·00	
4	H. G. Williams	Florence	24·25	12	13	16	14	8	87·25	
5	L. C. Roberts	Currawa	22·75	12	14	19	12·5	8	88·25	

a. Weight per bushel.
b. Plumpness and evenness of grains.
c. Freedom from visible admixture.
d. Freedom from bunt, weed seeds, etc.
e. Freedom from injury in harvesting.
f. Freedom from dirt, chaff, straw, etc.

Weight per bushel—25 points.

Varying from 59¼lbs. in two of the samples of Nabawa to 64lbs. for the exhibit of Quality, the average weight of all entries ran out at a shade over 61¼lbs. per bushel. The Florence was only a trifle behind the Quality in this regard, the entries of Currawa, consistently at midway, tipping the beam well above the general average, whilst the two light-weight submissions of Nabawa gave the impression of having been subjected to weather bleaching.

Plumpness and evenness of grains—15 points.

Noticeable variations in this respect occurred to a greater or less degree in all of the samples, though the general uniformity may be gauged by the average allocation of 12.3 points, an interesting factor being the varietal differences as between the group of Nabawa entries and of the collection of Currawa exhibits.

Freedom from visible admixture—15 points.

Although they may not be altogether definite proof of foreign grains, the presence of just occasional green kernels in the early wheats were viewed with suspicion, along with the one or two deeper coloured grains which showed up under close examination in others.

Freedom from bunt, weed seeds, &c.—20 points.

The samples right through displayed no sign of bunt either by sight or smell. Barley constituted the greatest menace in the way of weed seeds, one or two of the entries containing a number of barley seeds. Apart from these, a stray jack sharp and nancy were all that came under notice.

Freedom from injury in harvesting—15 points.

This was rather pronounced in some exhibits, more particularly with the bleached Nabawa grains.

Freedom from dirt, chaff straw, &c.—10 points.

There was little to complain of regarding dirt, but chaff and broken backbones were present in varying quantities in some of the samples.

BULK HANDLING.

[Paper contributed by Messrs. G. Freebairn and A. Dolling at the June meeting of the Snowtown Branch.]

The question of the introduction into Australia of some more economical system of handling wheat has come up for consideration from time to time for a number of years. It has become more urgent as the cost of cornsacks has increased and there has been a growing feeling that the absolute dependence of Australian farmers on the source of supply of sacks, principally India, is undesirable, apart from the matter of cost, and that sooner or later serious difficulty will be encountered if the supply should be interfered with for any reason.

Some years ago a system of bulk handling was introduced into New South Wales and this has been extended until most of the principal wheat growing centres are served by it. Bulk handling is not universally adopted in that State, however, and a proportion of the crop is still handled in bags but more silos are being constructed each year and only the smaller sidings are without bulk handling facilities.

So far as can be ascertained the system gives general satisfaction and while operating costs are met the conduct of the system has involved the New South Wales Government in some monetary loss in the past. The principal cause of the loss has been the high capital cost of installation; the New South Wales system has been modelled principally on American and Canadian lines and included substantial country silos and a terminal plant of considerable capacity at Sydney.

Several years ago a specially appointed committee closely enquired in the New South Wales bulk handling system on behalf of the Victorian Government but reported adversely on its introduction into their own State on account of the formidable outlay required.

The position in South Australia appeared even less favorable to the introduction of bulk handling on account of the smaller wheat yield than that in the Eastern States and the multiplicity of shipping ports.

The coming of the period of financial stringency resulted in the matter being shelved, apparently for an indefinite period, as the provision of the large sum of money required to inaugurate an effective bulk handling system seemed quite beyond the ability of any Government or private enterprise.

It has been left to the co-operative organisation in Western Australia, Western Farmers' Limited and the Western Australian Wheat Pool, to revive the matter and the results of their investigations and experiments have shown that an efficient scheme of handling can be economically conducted at most receiving centres.

There are two important factors which the Western Australian organisation apparently had regard to throughout; one is that wheat, being a low value commodity demands cheap means of handling and the other is that large terminal accommodation is not necessary, storage facilities being much cheaper to provide in the country than at shipping ports.

Experiments on a modified scale were conducted in Western Australia in 1931 and, aided by the knowledge gained thereby, it was decided to establish bulk depots at five points for the receival of wheat during the 1931/32 season. These depots proved very satisfactory.

Additional accommodation was provided for the 1932/33 season's harvest and the trials have been so satisfactory that a special company has been formed to install a comprehensive system to cover the main wheat producing areas in Western Australia and the constructional work is now in course of progress.

THE SYSTEM IN OPERATION IN WESTERN AUSTRALIA.

Ordinary wheat sheds are prepared for the reception of wheat in bulk by being strengthened by the introduction of additional posts and walled with galvanized iron or timber and sufficiently stayed. Concrete or wooden floors are also provided. To accommodate wheat received in excess of the shed capacity, temporary storage bins are constructed of timber and roofed with iron. These do not reach more than a few feet from the ground. Wheat for delivery in bulk is brought in by farmers either in bags, or box trucks, or wagons. Various devices are used for temporarily closing bags or they may be left unfastened.

After weighing over weighbridge the wheat is emptied into a bin or pit by the farmer who retains the bags for further use.

Elevators of a mobile and inexpensive type are used to move the wheat from the reception bin to the shed or direct into trucks as may be required. These elevators are also used for moving wheat from sheds to trucks.

Much of the rolling stock of the South Australian Railways could be adapted to the carriage of wheat in bulk without considerable expense. This applies especially to trucks on the broad guage lines.

It is probable that improved methods of transporting the wheat will be evolved both at the receiving depots and at shipping ports.

As far as costs are concerned, the experiments show that an appreciable saving can be effected under the system adopted in Western Australia. It is estimated that a saving of between twopence and threepence a bushel can be effected, calculating the cost of bags at recent values.

The inauguration has proved so popular amongs the farmers in Western Australia that the estimates of receivals were greatly exceeded, many farmers electing to cart their wheat past sidings where only bagged wheat was received in order to avail themselves of the bulk system. Some are said to have carted their grain as far as 30 miles to the bulk depot.

It will be realised that the provision of storage accommodation at shipping points is a most important factor in any bulk handling scheme. Suitable waterfront sites may be difficult to secure and will probably be costly to rent from the harbour authorities. If the proposed structures are to be high the cost of foundations necessary to support the very great weight would be considerable. In view of the extra despatch with which trucks could be loaded and unloaded, it is not considered that anything more than a reasonable reserve stock of wheat would be required at each port. The cost of making this provision should not be excessive.

The mobile elevators in use in Western Australia are capable of handling a ton of wheat per minute, the largest truck in use in South Australia could thus be loaded comfortably in one hour. The facility of transport thus achieved will be obvious.

Another point to be considered is shipping. Owing to the much more expeditious loading, shipowners are prepared to accept lower freights for bulk wheat, the time of loading is reduced to approximately one-sixth of that required under the bag system. The saving of freight would go far towards balancing the additional cost of handling the wheat between the point of delivery and ship's side.

Advantages of Bulk Handling.

1. Saving in cost of bags—at most one-third of the usual quantity would be required each year to transport the wheat from farm to siding—means can be devised to practically eliminate bags altogether. 2. Saving cost of sewing—twine and labour involved. 3. Independence of source of supply of sacks, *e.g.*, a strike of Indian jute workers or disorganisation of shipping. 4. Elimination of some af the present charges at receiving points, *e.g.*, provision of dunnage, curtains, &c. 5. Greater despatch at sidings through weighing in bulk and necessity of carrying wheat. 6. Elimination of waste at handling points, in railway trucks, &c. as is experienced at present. 7. Complete protection from damage by weather, mice, birds, &c. 8. Additional mobility gained by quicker loading and discharge of railway trucks. 9. Savings in overseas freight, at present 2s. 6d. per ton or approximately ¼d. per bushel. 10. Saving in labour costs at shipping ports. 11. Quicker loading of vessels.

There are certain points that should be particularly noted in regard to this question. 1. That it is not proposed that farmers should be compelled to utilise bulk facilities if provided, consequently any farmers who did not find it convenient or economical to deliver in bulk could adhere to the bag system. 2. There is a private concern willing to undertake the installation of a system of bulk handling at its own expense, therefore it is not necessary for any public money to be expended on the venture. 3. As public funds need not be involved there is no necessity for government control of the system. 4. Costs of handling under a bulk system controlled by private enterprise could not be excessive, they would have to be moderate to be competitive with present costs otherwise wheat would not be attracted to the scheme. 5. Buyers of Australian wheat in England and other countries are now prepared to pay as much for bulk as for bagged wheat, if there is any difference it is only very small, usually less than a farthing per bushel. 6. Australia is the only wheat exporting country of importance which has not adopted bulk shipment of wheat on a considerable scale. 7. Any scheme recommended for adoption in South Australia must take into account the different geographical conditions in South Australia and the Eastern States. A system that required costly terminal storage would be prohibitive here because of the many shipping ports used. For this reason the unorthodox system tried out in Western Australia is recommended for adoption in South Australia. Experience has proved that storage of wheat at many country receiving places is quite practicable under South Australian conditions; this point is important, and care should be taken to avoid comparison with North American conditions, which are very different from those in Australia because of the different climate which prevents the transport of wheat during certain parts of the year.

The Labour Position.

There has recently been some agitation on the part of the waterside workers at Port Adelaide and elsewhere against bulk handling because it would minimise the amount of labour required at shipping ports. While the feeling of the wharf labourers on this matter is appreciated, it cannot be conceded that because they may be adversely affected

that bulk handling should not be proceeded with. No such attitude has been adopted by labour interests in respect to mechanical handling of other commodities, such as coal, nor to the mechanisation of secondary industries generally, and farmers naturally ask why they should be selected to carry the whole burden of labour which has been rendered superfluous by the introduction of modern mechanical methods.

It is important that a too narrow view of this aspect of the bulk handling question should not be taken. The matter should be viewed from the broad aspect of the national welfare. The cost to the farmers of South Australia of the cornsacks required for a crop of forty to forty-five million bushels at recent prices will be something over £500,000. The greater part of this money goes out of Australia for cost of the sacks in India and shipping freight. It is estimated that if a complete bulk handling scheme were installed about £400,000 would be saved out of this cost. The whole of this money would remain in the State and would represent a saving to each of the 14,000 farmers in South Australia of nearly £30 on the average. This money would not be withdrawn from circulation, but would be spent by the farmers, much of it no doubt in labour for necessary repairs to farm improvements and so on, consequently the total amount of labour employed would be actually increased, although some would no doubt be diverted from the water-front into other channels. It should not be forgotten that a good deal of labour would be required for the erection and maintenance of bulk facilities in the country, and this would help to tide over the present period of acute unemployment.

May 30th.—Attendance, 16.

Clearing New Land.—Mr. M. Steinborner delivered a lecture on this subject, in the course of which he stated June and July were the most suitable months for clearing land, mainly for the value of wood, especially posts. The simplest and quickest method of pulling scrub down was with 4 horses and a heavy wagon or trolley. The chain should be slung around the tree as high as possible, and it was advisable to have a light load on the wagon to prevent it from lifting off the ground. For trees that were too strong for that method there were various other horse-power machines and grubbing jacks. Mullenising was not essential because it only half did the job; the stumps that were still in the ground ruined implements and team, and there was the trouble and bother of cutting and burning the young shoots every year. The wood and posts should be cut as soon as possible; if it was allowed to dry first it was much more difficult to cut. The rubbish left over should be burnt. If mullenising was done, the land should be cropped the first two or three years in succession and the stubble burnt, thus destroying shoots, roots, and all other rubbish. If time permitted stones should be carted off before cropping. Holes and ridges could be levelled off with a heavy iron drag. The same applied to ground that had been grubbed. (Secretary, R. Steinborner, Neale's Flat.)

NANTAWARRA (Average annual rainfall, 10.29in.).

May 31st.—Attendance, 14.

Hand Feeding Livestock.—Mr. K. Young read the following paper:—"When hand feeding is spoken of it usually refers to sheep, young horses, or cattle. At present sheep seem to be hand fed on most farms, especially ewes and lambs, for in most cases there is a shortage of good feed to enable the ewes to keep in good condition to supply the lambs with milk. If lambs have a severe setback when young it spoils them for marketing. We feed with long hay, chaff, pure corn, or corn and chaff. As to which method is best, depends largely on the purpose for which the sheep are required.

To most farmers, wool is one object they have in view. For wool, I favour long hay, it has enough strength in it to keep the sheep in fair condition. To allow them to get too low in condition would probably make a break in the wool, and the sheep would be more subject to disease. For fattening, they need a food of a better quality, preferably good chaff. To feed on pure corn is extravagant. Sheep all go for the best and will leave the poorer food. One farmer last year cut some patches of charlock that grew in the crop, and is at present feeding it to his sheep. The sheep are doing well on it, and by cutting these patches for hay, has turned what would have been practically useless rubbish into a useful fodder. It is sound practice to have in reserve enough fodder to feed to the sheep if required. There are different methods of feeding sheep. Some of the more fortunate have self-feeders, but from these, the stronger sheep get first pick, which is a disadvantage to the weaker ones. Others feed on clean hard ground, but mainly for hay. Iron troughs too are used. Super bags cut open with a wire threaded through each side holding the edges of the bags off the ground about a foot also make a good feeder. In some districts an ensilage pit would be handy, but this hardly seems practical considering the amount of labour entailed for a small quantity of ensilage.''

Discussion.—Mr. H. Paterson said a number of kerosene tins when each cut in half lengthways and tacked to boards made a splendid feeder, the wind not disturbing the feed. He also gave an instance where one of his neighbours kept about 700 sheep fat on a bag of peas daily. Mr. L. Belling spoke of his experience with chaff in the fleece when feeding on chaff, and favoured barley hay for sheep, they ate it in preference to wheaten or oaten hay. Mr. W. Starkey had fed Meggits meal to mares and foals and was extremely pleased with results. Peas also were a good fodder for sheep, the vines making splendid feed when dry. Mr. F. F. Herbert had an experience with sheep on peas and was pleased with the feeding qualities in the vines. Mr. K. Young replied and said it was well to feed roughage with rich feed, and when hand feeding, to feed well away from the drinking water if possible. (Secretary, S. Herbert.)

UPPER WAKEFIELD.

May 24th.—Attendance, 17.

The evening took the form of debate, "Horses *versus* Tractor." After both parties had expressed their views on the subjects the adjudicator (Mr. A. J. Marron) gave his decision in favour of the team representing "Horses" by the small margin of half a point. Mr. C. F. Neumann (Hon. Secretary) congratulated the younger members of the Branch on their fine efforts as debaters.

ELBOW HILL (Average annual rainfall, 11in. to 12in.).

May 29th.—Attendance, 15.

THE WORLD'S WHEAT POSITION.—Mr. G. Payne read a paper on this subject, and in the discussion that followed Mr. S. Wake said it was a pity farmers were holding up the export of wheat. Had there been a compulsory pool the whole of the wheat would have been shipped. They could not store wheat in South Australia like other parts of the world. Mr. W. T. Cooper thought tariffs the main trouble in regard to the wheat industry. France and Germany had put big duties on our wheat, and they had practically only one market left for wheat. Mr. John Rehn said it did not seem as though stored wheat was going to bring a big price. The Great War had made France and Germany think seriously of growing their own foodstuffs. The wheat position was in a very serious position at present. The old maxim of supply and demand was the main factor. He did not think huge surpluses of wheat existed. Mr. Bert Jacobs said farmers should organise and restrict areas sown to wheat. (Secretary, J. Wildman.)

GREEN PATCH (Average annual rainfall, 19.42in.).

May 24th.—Attendance, 8.

REGISTRATION OF EAR MARKS FOR SHEEP.—All sheepowners should study the new Brands Act which for the first time allows a registered ear mark. Mr. P. Sinclair stated that the whole of Eyre's Peninsula was taken as one district under the Act, and no two similar registered marks were allowed for the district, and as only one ear was allowed for the registered marking, viz., the near ear for ewes and off ear for male sheep, it would not be long before all the simple marks were taken. Any private marks or age marks could be used on the ear opposite the ear used for registered marks.

FOXES.—A discussion on their destruction was held. Rabbits' heads were considered a good bait, but it was thought by most members present that rabbit head was dangerous to the farm dogs as the fox often carried this bait some distance and left it uneaten. The most common bait used in this district was sheep's liver, the baits always being buried and the position marked with pegs. Mr. Bailey advised running a trail every three days, and using sheep's offal for a drag. Mr. Murray recommended a trail once a week using a scorched sheep's pelt for the drag. Mr. Bailey stated that baits not buried were generally picked up birds even at night time. He also stated that when foxes first came to this district they dug up and ate most of the young rabbit nests which were at that time only shallow. Now the rabbits did not nest shallow, but mostly in places where the fox could not dig out. He did not find that soda used with strychnine made any difference to the quick destruction of the fox. The dead fox when it took a bait was generally found up hill from where the bait was taken. Mr. P. Sinclair yarded his ewes and lambs every night in a small paddock having a foxproof fence of 6ft. netting. He had proved this a successful method of dealing with the fox question. (Secretary, C. Whillas.)

NUNJIKOMPITA, May 24th.

A paper entitled "Clydesdales" was read by a member:—"This breed of horses originated in Scotland, and is essentially a utility horse noted for his fine springy action and gay appearance, with a small lean head. The neck of a mare in good or show condition should show a distinct arch on the crest. Coming over sloping shoulders, this is one of the characteristics of this breed, *i.e.*, a long horse covering a lot of ground with a really short back. This type of horse is always well ribbed up, never slack across the loin, and seldom flat-ribbed, though age always brings the ribs flat in time. Coming over the rump there is a breed fault; the drop to the tail is a bit too steep. The legs are the most important part of a utility horse. The feet should be big, but keeping yearlings and two-year-olds shod to develop an excess of hoof is one of the mistakes of the stud masters of to-day. Fetlocks should be long and well sprung. Many of the very high class Clydesdales I have seen in Scotland would, in South Australia, be classed as 'down in the fetlocks.' Cannon bone should be long and fat, having a hard smooth feel, with joints between fetlock and cannon free from knots or lumpy feeling. Hair should be fine, long, and straight, and confined to the back of the leg, leaving the front with little more than the ordinary coat carries. Straight hocks without any tuft give an appearance of capped hock, which is a serious fault. This class of horse seldom has the appearance of pot-belly. A chest too broad is as bad as one too narrow, setting the legs too far out instead of being under his weight, generally giving a paddling action that tires the horse. Looking at the girth, it should be set well back from the arm; a horse girthing close up always has a tendency to girthgall. Clydesdales are becoming noted for their white markings, the tendency being to breed more and more white on

to them until it seems to be becoming a hall mark of high class to carry an excess of white. When buying or choosing a sire for service, do not have anything to do with a horse with a vicious temper, and treat a mare the same way, for nothing comes out surer than the disposition of the parents of the stock.''

On April 29th Mr. W. H. Brownrigg (District Instructor) delivered an address, ''Horses, Cattle, and Pigs.'' (Secretary, P. Luestner.)

On Mr. C. F. Jericho's Farm, at Butler, thousands of Seagulls completely wiped out an infestation of grasshoppers which had caused so much damage to wheat crops and pastures.

WALLALA.

May 9th.—Attendance, 7.

PRODUCER GAS.—The Hon. Secretary, Mr. C. Zippel, read the following paper:—''During recent years efforts have been made by farmers to reduce the cost of production in an endeavour to make wheatgrowing profitable. For the man with a tractor. the adoption of producer gas has proved a step in the right direction, and has enabled fuel costs to be considerably reduced. The Mallee districts where there is an abundance of wood, suitable for charcoal, afford excellent opportunities for reducing the costs by the use of producer gas for power purposes. It will be admitted that when using producer gas, the engine loses a slight percentage of power and is a little more inconvenient to operate, but it must also be taken into consideration that when one can operate the engine for much less than half the cost of when working on liquid fuel, the inconvenience can well be afforded. I have now had 18 months' experience with producer gas plants and find the chief factors towards the successful operation of these plants are the use of clean and not over-burnt charcoal, and secondly, thorough daily attention to the scrubbers. Care should be taken when burning charcoal (especially when using the pit method) to see that the wood is not burned too quickly; this will result in a very poor sample of charcoal. The kiln method is the best to obtain good clean charcoal. The scrubber of the producer can be considered as the part of the plant requiring the most attention, for unless the scrubber is thoroughly clean and filled to the correct levels it cannot give the best results. Trouble will occur by either causing loss of power or by allowing uncleaned gas to find its way into the cylinders of the engine and thereby causing damage to the cylinder walls and pistons. Throughout the year an account has been kept of the costs per acre of working a 2-ton tractor fitted with a gas producer, and are as follows:—Ploughing, 4d. per acre, using 12-furrow plough; cultivating, 2d. per acre, using 20 combine; combining, 3d. per acre, using 20 combine; reaping, 4d. per acre, using 8ft. header. *The Kiln Method of Burning Charcoal.*—Build a round stack of wood (preferably green) on the ground measuring about 9ft. in diameter. After making provision for the necessary ventilation cover the stack of wood thickly with leaves and earth. Light in the centre of the kiln, it will then take about 30 hours before the flames emerge from the vents, which are then closed down. The kiln is then left for about 70 or 80 hours to cool sufficiently before being opened up with safety. If not properly cooled down, there is the danger of the stack bursting into flame again as soon as the air is let in. A kiln of the abovementioned size usually produces from 12 to 15 bags of screened charcoal. I find that the same acreage can be obtained from 1 bag of good charcoal as from 1 tin benzine.''

SHEARING AND PREPARING THE CLIP.—Paper read by Mr. H. Brown:—''The two main points in blade shearing are holding the sheep in the right position and sharpening the shears. Sheep should always be handled carefully when shearing. On most farms—

with only a small flock—the rams are allowed with the flock all the year round and some of the ewes are in lamb at shearing time and if handled roughly there is a danger of losing the ewe as well as the lamb. Care should be taken when shearing around the udder to see that the teats are not cut. In preparing the clip for market the fleece should be thrown out on a large table, the back taken out, and a separate fleece made of it. The rest of the fleece should be skirted only lightly, the stained pieces removed from the legs and around the crutch. The sides and shoulders produce the best quality wool. On no account should the belly wool be put with the fleece. It is not necessary to keep each sex wool separate if the back is taken out. If the back is not taken out, the parcel offered is two different classes. By taking out the back which contains more sand than the sides the sand is not mixed among all the wool and it can be offered in a much more attractive lot."

THE SHEEP BLOWFLY.

[*Paper read by Mr. F. Parsons at the June meeting of the Kelly Branch.*]

The flies that are responsible for striking sheep are not native to Australia, but were imported accidentally during early settlement.

A fly passes through four stages—egg, larvae, pupa, and adult. Approximately 1,000 eggs will be laid by a female fly. These hatch out in 1 or 2 days. Certain species never lay eggs but deposit young, active maggots.

Blowfly larvae or maggots exist in two distinct kinds—smooth maggots and hairy maggots. These two types are important because they form a valuable means of controlling the pest. The smooth maggots belong to a primary species of fly and hairy to a secondary species. The head of the smooth maggot has a mouth on the underside of the head, and jaws can be extruded in the form of two parallel black hooks. These serve to tear food into small pieces, actual feeding is chiefly done by eating liquified food. The hairy maggots have a more superior method of progression and mouth hooks are pointed and stronger formed than smooth maggots.

Experiments conducted at Canberra have proved that the maggots of the primary fly are first deposited on the sheep or carrion. The secondary fly will not lay eggs

Crutched sheep—Correct way.

unless the sheep has been already struck with the primary fly. The hairy maggot is a natural enemy of the smooth maggot, and when full-grown will attack and eat it, thus diminishing flies capable of striking sheep.

However, the sheep is worse off than before, because hairy maggots are much more active and will burrow far deeper into the body of its host. In summer, the period from egg to adult may be as short as 10 days.

The fly may be divided into two classes—those that strike first, called primary flies, and those that do not strike until after the sheep has been struck, secondary flies. In the first division are the primary green blowfly, the large brown blowfly, and the Western Australian brown blowfly.

In the secondary division the most important is the secondary green blowfly, distinguished from the primary green fly by dark bands crossing the abdomen. Primary flies fly about 8 miles in 17 days, while secondary flies fly 10 miles in 12 days. The life of a fly is from 35 to 91 days.

Methods of Control.

Practical control may be divided into two divisions—the prevention of strike, and cure of sheep once struck. The prevention of strike can be helped by decreasing the number of flies. As maggots can obtain full development only by feeding on carrion and living animals, it follows that all carcasses should be burnt. If buried the hole should be deeper than 6ft., because primary maggots have been known to reach the surface from this depth.

Crutching has proved its value many times over. The reason for this can be seen when it is realised that the strongest sense the blowfly possesses is that of smell. Under favourable conditions the Council for Scientific and Industrial Research has shown that the blowfly will deposit eggs on saddle cloths and blankets. Jetting and dipping in certain instances have been most beneficial. In my opinion trapping is not very satisfactory.

Selecting Sheep Susceptible to Strike.

By far the best method to prevent fly attack is to breed or select sheep that are not susceptible. It has been proved at Canberra that flies do not strike sheep at random, but because of the development on the sheep of an area of susceptibility, or that liability to strike is fundamentally dependent upon some factor in the sheep itself. In New South Wales careful records were kept of sheep struck, and it was found that practically the same sheep were struck each season. After examining the conformation of these sheep it was found that the liability to strike was parallel to the degree of wrinkling around the crutch. Thus, sheep having wrinkles around the crutch should be avoided as much as possible.

Crutched sheep—Incorrect way.

Some figures published in New South Wales of a private property are interesting. A flock of 2,450 ewes was divided into three and classified as follows:—Flock A (relatively insusceptible), 1,121; flock B (moderately susceptible), 872; flock C (definitely susceptible), 457. The number struck were:—Flock A, 1 sheep in 21; flock B, 1 sheep in 6; flock C, 1 sheep in 2. Some sheep in C were struck as many as 20 times in one season.

The infolds of these wrinkles are essentially places wherein moisture from urine, sweat, and rain is retained. Bacterial decomposition of yolk, sweat and skin exudations are thereby favoured, and bacteria growing on such areas may cause a definite inflammatory condition of the skin. Such areas give off a smell which is naturally attractive to blowflies. Sheep which are narrow behind and have their hocks approaching each other, are more prone to be struck than are wide, open-hocked sheep.

Wool condition is also related to some extent, for, in general, the wool of susceptible sheep carries more condition. It might be thought that the wool would suffer if sheep were bred that are "fly proof," but the A division in the example given contained a larger percentage of top line wool than the others. The "susceptible" group's wool tended to be finer and more heavily conditioned, yet wool of this type is carried by a fair percentage of sheep which are not struck. With our own flock with lambs by a Merino ram, we had to get them in practically every day during October, 1931. After

introducing Corriedale rams and crutching in February we have had only about 6 cases since the 1933 shearing. The top of the ear of nearly every ewe that is struck is nipped off, and it is usually these sheep that are the most troublesome. When fit they are killed for rations. In our case the wool has deteriorated slightly, but we have better shaped lambs.

The mating of A class rams with A class ewes from the divisions in the table gave lambs that were much less susceptible to flies than lambs from either of the other divisions. The question might be asked if susceptible sheep are bred out of the flock, will not the fly strike the less susceptible ones? The answer, according to New South Wales experts is that certain conditions appear to be necessary for the development of maggots on sheep, and it is the presence or absence of these conditions which seem to determine whether fly strike will take place. These conditions are a factor of the individual sheep and are not influenced by the fact that other sheep are running with it. Keeping sheep yarded unnecessarily is to be avoided, and all yarding reduced to a minimum when flies are troublesome. Adequate water supplies should be available so that sheep do not have to wait about for a drink, and also plenty of shade provided so that sheep do not crowd together.

TREATMENT OF STRUCK SHEEP.

A sheep that has been struck can be detected by any of the following points:— Sheep wriggling tail and stamping hind feet, or bending head round and biting at flanks. Fly blown sheep generally walk at the end of the mob.

When caught, the wool should be shorn well away from the affected area, and as close as possible to the skin. All maggots should be scratched out, care being taken that they do not fall on any other part of the sheep.

The best and cheapest dressing for this district is sump oil and powdered sheep dip. The maggots can only take their food in a liquid form so that as the sheep dip remains on the wool for a long time, any future maggots stand a fair chance of being poisoned. The sump oil acts as a protective coating on the wound and counteracts the caustic action of the sheep dip.

The dressings recommended by the Council for Scientific and Industrial Research after much experience are:—(1) 5 per cent. solution of zinc sulphate. (2) 5 per cent. watery solution of Monsol. (3) 4 per cent. phenol (carbolic) crystal in whale oil.

If plain-bodied sheep are kept and crutched during summer, very little trouble should be experienced in this district.

May 19th.—Attendance, 26.

RABBIT DESTRUCTION.—Mr. H. B. White read the following paper:—"No matter what kind of rural production a person may take up, he will find that there is usually some pest that has to be dealt with. The horticulturalist has to contend with birds and insect and fungus parasites. The beekeeper has to guard against ants, waxmoths, &c., but to the farmer and the pastoralist the worst pest is the rabbit. This animal is not a native of Australia but was introduced from England by early settlers. The rabbit found our land very much to his liking and within a short period spread over the whole

of the country in such numbers as to constitute a menace. Considerable damage can be done by rabbits where they are plentiful. They nip off acres of wheat or other cereals if allowed to thrive in close proximity to a crop. After the crop is ripe they continue their work of destruction by nipping through the stalks and allowing the head to fall on the ground. On grass land they destroy much good feed. It is claimed that 8 rabbits will consume as much feed as 1 sheep, so that the extent of the loss that a landholder may incur through rabbits decreasing the carrying capacity of his paddocks is quite obvious. It is therefore in his own interests that the landholder should do something every year to keep this pest in check. In most ills prevention is better than cure, and this applies to rabbits, for a farmer can save himself much trouble if he clears all his patches of scrub. This may not be practical in some of the rocky country that is found in this district, but in sandy land I consider that this is best. Where scrub is left on sand ridges, the edges of it soon become banked with drift sand and thus form an ideal place for rabbits to make their warrens. Most scrub land is infested with rabbits, and their warrens are numerous, but as soon as the scrub is properly cleared away, and the warrens ploughed in (with a tractor for preference) no more trouble is experienced with them. Various methods are adopted for the destruction of rabbits, such as fumigating the burrows with cyanide gas and laying poison, but the cheapest and perhaps most effective method is to place poisoned oats about in infested country. Rabbits are very partial to oats, and if treated for several days with unpoisoned oats will take to the poisoned ones quite readily. This work can only be carried out effectively when all natural grasses are dry. Care must also be taken to see that no farm stock is about, otherwise they may become poisoned also. After the poisoned oats have been out for several days they should be collected and destroyed. This is an easy matter if they are put out in small heaps of a handful and the locations of each heap marked with a stroke on the ground. To poison the oats, put them in a solution made of strychnine and water and heat to almost boiling point. In this way the oats become thoroughly saturated. When there is plenty of greenfeed about I consider the most effective way to destroy rabbits is to trap them and then dig in their warrens. This method has this advantage, viz., you can collect the skins, and by selling them reimburse yourself to some degree for the trouble you have been put to.'' (Secretary, C. Altmann.)

May 26th.—Attendance, 11.

Poultry Keeping, with Special Reference to the Black Orpington.—Paper read by Mr. J. Stone:—''Assuming that we have a place suitable to house the birds, the next thing is to determine in what manner we will proceed in securing a flock. Possibly it will be decided to go to a reputable breeder and procure a pen of birds for breeding—a cockerel and six hens—of a good strain. On the other hand, chicks of a first class strain may be purchased. This is cheaper in initial outlay, but by the time the birds come to laying eggs, will have cost a fair amount, and possibly some chicks have died, thus adding to the cost. Any young cockerels will be ready for market at about six months old. If rearing a flock, there will be a wait of 12 months from when the pullets start to lay before they can be used as breeders, also a cockerel will have to be purchased; breeding from closely related birds is not an amateur's job. Breeding from pullets means deterioration. The eggs are small both in size and numbers, and birds have far less vitality. The best proposition is to buy a pen of good birds and rear from them. It will be found necessary to have them mated three weeks before starting to keep eggs for incubation. For the first year procure broody hens for hatching purposes, because by the time there are enough eggs for an incubator some of them will be too stale. It is not advisable to incubate an egg over seven days old;

the strongest chickens are hatched from the freshest eggs. At the mating period give the birds a little extra attention and see that they have all that is required to give them plenty of vitality and ensure strong healthy stock. When the chicks are hatched, do not be over anxious to feed them until they are from 36 to 48 hours old and then start them with finely broken shell grit. Then give any of the proprietary foodstuffs which are all good for about a week, then they can be fed finely cracked wheat and finely chopped greenfeed. Gradually as they grow older bring them to the ordinary foods at about two months old. It will be found best to keep the chicks from the rest of the flocks, as sometimes older birds appear careless to chicks and injure and kill them. Any chicks that are not strong and healthy are not worth bothering with; even should they live, they are only weaklings all their life, and are not payable. When the chicks are old enough to define the sexes, separate the cockerels from the pullets. Keep the young birds in warm houses to which is attached a small run so that they may have all the sun and exercise they require in good weather, but if wet, keep them in the house with plenty of straw on the floor for scratching. In this manner keep them well exercised while still young, so that the birds will develop fully. As the cockerels approach the age of four or five months pick out the most forward birds and put them in a fattening pen, where they can be topped up for market in about three weeks. This pen is quite small, being only large enough to hold about a dozen birds, with very little room to move about, but to keep quiet and put on all possible weight in a short period. A pen for fattening must necessarily be warrm in winter and cool in summer, and on no account must it be draughty. Make the back and one side of wood, leaving the front and one side to be wire-netted, over which a shutter can be used as found necessary. The roof should be of some waterproof material, the floor of wire-netting of small mesh and heavy gauge. A tin used as a tray is placed under the netting to catch all droppings, which should be cleaned away daily. All food fed to birds for fattening in a pen is in liquid form, and given quite fresh. No water is used separate from that used in making the food liquid. Old birds that are discarded as layers will be quite palatable if finished off for market in this manner. As in the case of young birds for fattening, a change in the food should take about a week; if done suddenly, ill-effects will result. Black Orpington pullets usually lay their first eggs at from five to six months of age. These eggs are usually small for a start, but from a month to six weeks after the eggs are of a marketable size. We find Black Orpingtons the best winter layers. After a hen has had two laying seasons, it is only in rare cases that she is worth keeping longer.'' (Secretary, R. Stone.)

HOPE FOREST.

June 4th.—Attendance, 13.

Mr. W. J. Wilson, manager of the Kuitpo Hardwood Mills, in the course of an address said the most popular hardwoods in South Australia were pink and blue gum and stringy bark. Stringy bark was used mostly for sheds, posts, sheep runs, and water wells, because it was cheaper than other timbers. Thousands of feet of pink and blue gum were used for railway sleepers. Blue gum was the best timber for wells, mainly because it did not stain the water. He also specified stringy bark for posts in swampy land, stating that it would last 14 to 15 years, where other timber would rot away at ground level in 5 years. Within the next 10 to 12 years he believed there would be a shortage of hardwoods in South Australia. (Secretary, R. Coad.)

GOOD THINGS FROM THE OVEN.

[By GRACE B. ARMSTRONG, A. MARIE SCHRIEBER, and MARY A. MCPHEE, of the University of Illinois, Urbana, U.S.A.]

(*Continued from page* 1641.)

WAYS OF USING DRY CAKE.

CAKE SERVED WITH SAUCE.

Cut the cake in pieces the proper size for one serving. Quickly dip each piece in cold water. Place on baking pan 2 inches apart. Put into hot oven for a few minutes until the cake has freshened, or put the dry pieces of cake on a plate in a steamer and steam until soft. Serve with lemon or chocolate sauce.

PUDDING MADE FROM CAKE.

Equipment.

1 mixing bowl	2 teaspoons
1 saucepan	1 tablespoon
1 measuring cup	1 baking dish
1 egg beater	

Materials.

2 c. stale cake crumbs	2 eggs
½ c. stale bread crumbs	½ t. salt
1 qt. scalded milk	1 t. vanilla
2-4 Tb. sugar	½ c. raisins or currants
2 Tb. melted butter	¼ c. nuts may be added

(The amount of sugar, butter, and flavouring used will depend on kind of cake.)

Amount: 8 large servings.

Method.

How.	*Why.*
Scald milk	Crumbs will absorb hot milk more quickly and thoroughly than cold milk.
Soak bread and cake crumbs in milk.	The more thoroughly the crumbs absorb the milk the more perfectly they can be mixed with the other ingredients.
Add sugar, butter, slightly beaten eggs, salt, and flavouring.	
Add raisins and nuts	If plain cake is used, raisins and nuts may be added at the last.
Bake 1 hour in buttered baking dish in slow oven (300°F.).	This pudding requires the same care in baking as does a custard.
Serve with lemon or hard sauce.	

QUICK BREADS.

In making quick breads, different proportions of flour and liquid are used. Typical proportions are illustrated in the following:—

Batters: (1) Pour batter—1 c. liquid to 1 c. flour (popovers)
(2) Drop batter—1 c. liquid to 2 c. flour (muffins)

Doughs: (1) Soft dough—1 c. liquid to 3 c. flour (cake)
(2) Stiff dough—1 c. liquid to 4 c. flour (pastry or yeast bread)

Muffins, baking-powder biscuits, griddle cakes, and popovers are representative of the various types of quick breads. In making them we learn the fundamental principles of making all quick breads. Variations of these recipes emphasize these principles and give some additional processes.

MUFFINS.

Equipment.

1 measuring cup	1 mixing bowl
1 teaspoon	1 strainer
1 tablespoon	Muffin pans
1 flour sifter	

Materials.

2 c. flour	1 egg
3½ t. baking powder	1 c. milk
½ t. salt	2 Tb. melted shortening
2 Tb. sugar	

Amount: 12 muffins.

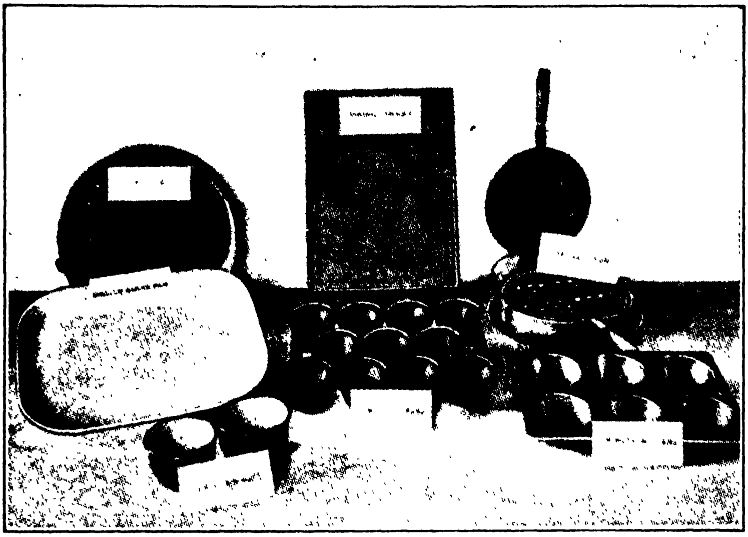

Fig. 6.—Utensils for baking some of the Quick Breads.

Method.

How.	*Why.*
Sift dry ingredients together.	Sifting the ingredients mixes them evenly.
Beat egg.	Beating breaks up the yolk and white so that the egg can be more evenly distributed. Egg is used here for a binding substance.
Add milk to egg.	The small amount of egg can be more evenly mixed if it is put in with the milk.
Gradually stir milk and egg into dry ingredients.	If the milk and egg are stirred in gradually, the mixture will not lump so easily.
Stir until mixture is free from lumps.	Stirring removes lumps and gives a finer and more even texture to finished product.
Add melted fat and beat about ½ minute.	Melted fat can be more evenly distributed than cold fat, but care should be taken not to brown the fat in heating.
Fill the greased muffin pans half full of mixture and bake in hot oven (410°F.) about 25 minutes.	Filling the cups only half full gives the muffins room to rise.
If there is not enough of the mixture for all the cups, partially fill empty ones with water.	Water prevents heat from injuring pan.

VARIATIONS OF MUFFINS.

Corn Meal or Graham Muffins.—Use same recipe as for plain muffins, substituting 1 cup of either corn meal or graham flour for 1 cup of white flour.

Sour Milk Muffins.—Sour milk or buttermilk may be used in place of sweet milk, with only a slight change of recipe. Follow the above recipe, using 1 cup of sour milk instead of 1 cup of sweet milk. Use 1½ instead of 3½ teaspoons of baking powder, and add ½ teaspoon of soda to neutralize the acid in the sour milk. (In any recipe calling for sweet milk and baking powder, sour milk may be substituted if soda is added. Use ½ teaspoon of soda for each cup of sour milk and subtract 2 teaspoons of baking powder from the amount called for in the recipe for each ½ teaspoon of soda used.)

Dried Fruit Muffins.—Add ½ to ¾ cup of currants, chopped raisins, or dates to the batter. Save out a little flour from the amount called for to mix with the fruit. This keeps the fruit from sinking to the bottom of the pan.

Fig. 7.—Graham Muffins.

Blueberry Muffins.—Use only ¾ cup of milk and add 1 cup of blueberries. Save out ¼ cup of flour from the amount called for to mix with the berries before they are added at the last. Flour is mixed with the berries to keep them from sinking to the bottom of the pan.

BAKING-POWDER BISCUITS.

Equipment.

1 mixing bowl	1 tablespoon
2 knives or 1 fork	1 flour sifter
1 biscuit cutter	1 breadboard
1 teaspoon	1 rolling pin
1 measuring cup	Baking pans

Materials.

2 c. flour	2 Tb. shortening
4 t. baking powder	½ to ¾ c. milk
½ t. salt	

Amount: 15 small biscuits.

Method.

How.	*Why.*
Sift dry ingredients together into bowl.	The baking powder and salt are thus evenly distributed throughout the flour.
Cut shortening into dry ingredients, using either a fork or 2 knives, until mixture is like coarse meal. One can work in shortening with tips of fingers.	A knife or fork keeps the mixture colder. If the hands are used, only the very tips of the fingers should be used and the mixture should be handled as little, as lightly, and as quickly as possible.
Push flour to one side of bowl; turn in a little milk and toss flour and milk together lightly with a fork until mixture is a soft dough. Continue adding milk gradually until mixture is a soft, spongy dough.	Some flours take up more moisture than others, so entire amount of milk called for may not be needed.
Turn on to slightly floured board, knead ½ minute, pat and roll very lightly to ¾in. thickness.	If mixture is handled roughly or rolled hard, the air bubbles are broken and the biscuits will not be light or fluffy. Excessive rolling and mixing develops gluten and so makes biscuits tough.
Dip biscuit cutter in flour and cut dough into biscuits, wasting as little of dough as possible.	Flouring cutter prevents dough from sticking to it. Pieces left after cutting are never so tender when worked over a second time.
Bake in very hot oven (450°F.) 12 to 15 minutes.	

Fig. 8.—Baking Powder Biscuits.

VARIATIONS OF BISCUITS.

Emergency Biscuits.—These biscuits are made according to the above recipe except that about ¼ cup more milk is used and the mixture is dropped from a spoon directly upon the oiled baking pan without rolling.

Pin Wheel Biscuits.—Use same equipment as for baking-powder biscuits except for addition of knife or food chopper.

Materials.

Baking-powder biscuit dough	2 Tb. sugar
½ c. chopped raisins or currants	2 Tb. melted butter
½ t. cinnamon	

Roll dough about $\frac{1}{3}$in. thick and spread with melted butter. Mix cinnamon with sugar, and dust on dough. Scatter currants or raisins on the dough and roll it up as for jelly roll. Pinch edges together so fruit will not fall out, and cut in slices about 1in. thick. Place slices on oiled pan and bake about 15 minutes in hot oven (425°F.). Watch the biscuits carefully, as the sugar makes them burn easily on the bottom.

Roly Poly.—

Materials.

Baking-powder biscuit dough	$\frac{1}{3}$ t. cinnamon
2 large apples, sliced	1 Tb. butter
$\frac{1}{4}$ c. sugar	

Use recipe for baking-powder biscuits, but use 3 tablespoons of shortening instead of 2 to make product richer and more suitable for dessert. Roll dough into an oblong shape $\frac{1}{4}$in. thick; spread first with softened butter and then with sliced apples, keeping apples about $\frac{1}{2}$in. from edge. Mix cinnamon and sugar, and sprinkle over apples. Roll up like jelly roll. Place roll on greased pan and bake in hot oven (425° F.) about 25 minutes, or until apples are tender. Other fruits may be substituted for the apples. Serve hot with sugar and cream, or pudding sauce.

Fruit Dumplings.—Use same recipe as for roly poly, that is, a baking-powder biscuit dough which has had an extra tablespoon of shortening added. Roll $\frac{1}{4}$in. thick, and cut in 5 or 6 equal portions, the size being determined by size

Fig. 9.—Pin Wheel Biscuits.

of fruit to be used. Place in the centre the apple or other fruit, pared, cored, either sliced or whole, and sprinkle with sugar and cinnamon. Moisten edges of dough with cold water and fold neatly together about the fruit. Bake or steam until fruit is tender. If cored apples are used whole, the centre may be filled with raisins or nuts, or sugar and cinnamon; or filling may be omitted. Brushing the outside of the dumpling with melted butter and sugar or with a little beaten egg before baking, gives a brown, glazed surface. Serve with pudding sauce, or sugar and cream.

Dutch Apple Cake.—Use same recipe and materials as for roly poly but roll dough a little thicker—about $\frac{1}{2}$in.—and place flat upon greased pan. Spread melted butter or other shortening on dough, and press sliced apples into dough in rows, with sharp edge of sliced apple downward, until top of dough is covered with apples. Mix cinnamon and sugar and spread over top. Bake in hot oven (425° F.) for about 30 minutes. Peaches or other fruits may be used in place of apples. Serve with sugar and cream, or pudding sauce.

Shortcake.—Use same recipe as for baking-powder biscuits, but use twice as much shortening to make product richer and more suitable for dessert. This means that 2 tablespoons of shortening are used for each cup of flour. The dough may be cut and baked in biscuit shape, or it may be baked in one large piece. If baked in large piece, it should be split with a fork after baking; cutting the hot product with a knife tends to make it heavy. Spread layers with melted butter and put sweetened fruit between layers and on top. Strawberries are always the favourite fruit, although raspberries, cherries, stewed dried apricots, oranges, or bananas may be used successfully. The top may be spread with whipped cream if desired.

GRIDDLE CAKES.

Equipment.

1 spatula or pancake turner	1 tablespoon
1 measuring cup	1 mixing bowl
1 teaspoon	1 small bowl
1 flour sifter	Griddle

Materials.

2 c. flour	1 egg
½ t. salt	1½ c. milk
3½ t. baking powder	2 Tb. shortening

Amount: 14 cakes about 4in. in diameter.

Method.

How.	*Why.*
Heat griddle.	A hot griddle forms a tender crust, searing the cakes and expanding the product before the gas bubbles can escape.
Sift dry ingredients together into mixing bowl.	This distributes the baking powder and salt evenly through the flour.
Beat egg in small bowl and add milk.	Mixing the egg with milk distributes it evenly through the mixture.
Pour milk and egg gradually on to dry ingredients, beating only until thoroughly mixed.	Beating gives the mixture a finer texture, but prolonged beating after the baking powder is added makes the cakes heavy and tough.
Add melted fat and beat again. Grease griddle lightly.	Melting the butter distributes the fat.

To bake, pour on hot, greased griddle. When cake is puffed full of bubbles and is brown on underside, turn and brown on other side. (Place on hot plate and serve at once.)

If large bubbles rise at once to the top of the cake, the griddle is too hot; and if the top of the cake stiffens before the underside is brown, the griddle is not hot enough.

Never turn a cake twice, for that makes it tough.

An aluminum griddle need not be greased.

VARIATIONS OF GRIDDLE CAKES.

Sour Milk Griddle Cakes.—Sour milk may be substituted for sweet milk in the above recipe. For proportions of baking powder and soda, see note under "Sour Milk Muffins."

Corn Meal Griddle Cakes.—Use same equipment as for griddle cakes except for addition of double boiler.

Materials.

½ c. corn meal	½ t. salt
2 c. scalded milk	1½ t. baking powder
½ c. flour	1 Tb. sugar
1 egg	1 Tb. shortening

Amount: 15 cakes about 4in. in diameter.

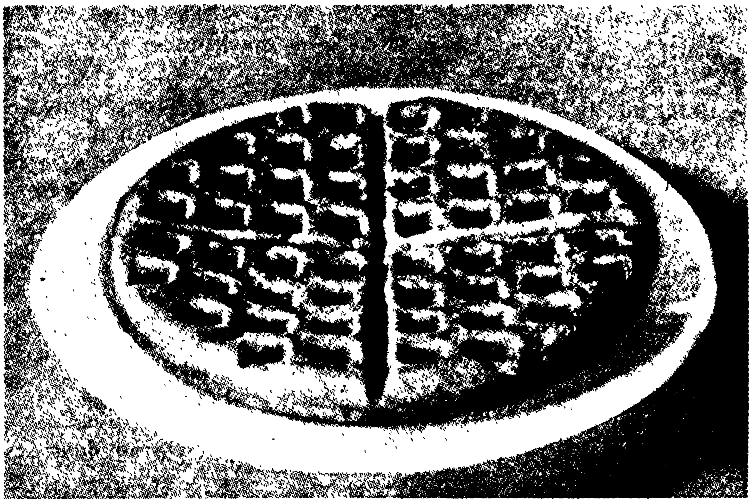

Fig. 10.—Waffles.

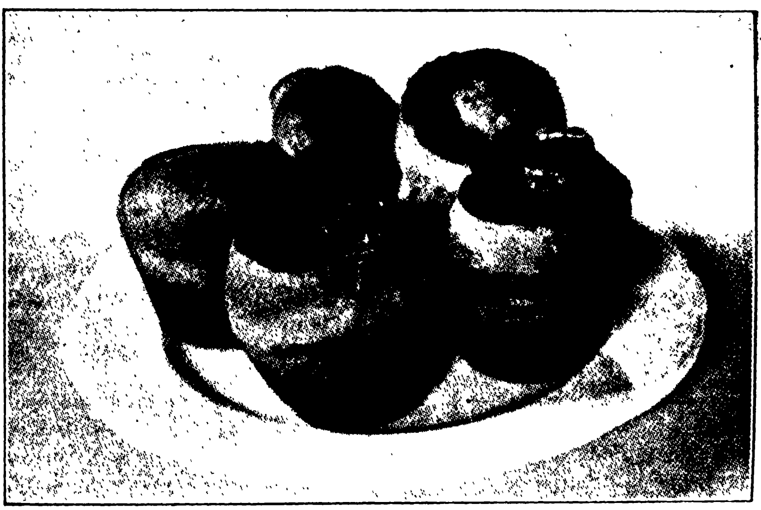

Fig. 11.—Popovers.

Method.

How.	*Why.*
Pour scalded milk over corn meal and stir well. Cook for 15 minutes in top of double boiler.	Being granular, corn meal needs longer cooking. This makes it more palatable and digestible.
Mix as for griddle cakes.	The same principles are involved as in making plain griddle cakes.
Cool slightly before adding beaten egg.	Mixture is cooled to prevent coagulation of egg.

Bake as griddle cakes. Care is required to turn these cakes without breaking.

Waffles.—Use same equipment as for griddle cakes, except substitute waffle iron for griddle and pancake turner. A pitcher from which to pour batter is a convenience.

Materials.

2 c. flour	2 eggs
2 t. baking powder	1½ c. milk
½ t. salt	2 Tb. melted shortening

Amount: 4 waffles 8in. in diameter.

Method.

Mix according to directions for plain griddle cakes. A lighter product will be obtained if yolks and whites of eggs are beaten separately and the stiffly beaten whites cut and folded in at the last. Beaten eggs act as a leavening agent; hence less baking powder is needed. Thoroughly heat the waffle iron. Grease it unless an aluminum or electric iron is used. Pour batter in centre and the mixture will spread to fill the iron. Brown waffle on both sides.

POPOVERS.

Equipment.

1 measuring cup	1 teaspoon
1 flour sifter	1 mixing bowl
1 Dover egg beater	Popover pans

Materials.

1 egg	1 c. bread flour
1 c. milk	¼ t. salt

Amount: 8 popovers.

Method.

How.	*Why.*
Use heavy earthenware cups, or iron or cast aluminum popover pans; agateware may also be used. Grease cup, using soft paper, cloth, or pastry brush.	A heavy material maintains more uniform temperature and forms better crust. Greasing prevents popovers from sticking to pans.
Start heating pans.	Pans should be hot enough to form a crust as soon as popovers are put into them.
Break egg into bowl and beat with Dover egg beater.	Egg is used here as a binding substance. A Dover egg beater beats more quickly than a fork or spoon and mixes the white and yolk more thoroughly.
Add milk and beat again.	Beating mixes the milk and egg so that the egg will be distributed evenly.
Add sifted flour and salt, and beat thoroughly several minutes.	Mixture is beaten well in order to remove lumps, and to make it smooth, thus giving a finer texture to the finished product.
Pour into hot, greased pans, filling them ½ to ⅔ full.	Room must be left in pans so that popovers can rise without running over.
Bake in hot oven (425°F.) at least 35 to 40 minutes.	A hot oven is needed to expand liquid quickly into steam and to form a crust which will keep its shape.
Do not open oven door for first 15 minutes.	If cold air strikes mixture before crust is set, the steam on the inside condenses and popovers will fall.

CREAM PUFFS.

Cream puffs are a variation of popovers.

Equipment.

1 measuring cup
1 mixing spoon
1 saucepan
1 sharp knife
Baking pans

Materials.

1 c. boiling water
½ c. butter
3 eggs
1 c. flour

Amount: 12 small or 9 large cream puffs.

Method.

How.	*Why.*
Heat the oven.	This mixture should begin baking as soon as it is placed in the oven.
Put butter and water in saucepan and bring to boiling point.	Fat melted in water tends to prevent lumping when flour is stirred into boiling water.
When boiling, add all the flour at once; stir vigorously until smooth.	The motion of rapidly boiling water and melted fat prevents lumping, while the heat cooks the mixture quickly. A stiff mass results that will stir together into a pasty lump.
Remove from fire as soon as mixture leaves sides of pan, and cool slightly.	The mixture is very thick and will burn quickly. It must be cooled slightly before stirring in the eggs to prevent the eggs from coagulating.
Add unbeaten eggs one at a time, beating mixture thoroughly after each egg is added.	It is necessary to beat the mixture to mix it thoroughly with the egg. Air and steam are the only leavening agents used.
Drop from spoon on to greased sheet, spacing drops 1½in. apart. Shape with spoon until circular, piling mixture slightly in centre.	Shaping the mixture will give it a rounded form rather than a flat one and will make it suitable for filling.
Bake 30 minutes in moderate oven (375°F.).	A hot oven would toughen an egg mixture.
Be careful not to remove puffs before they are done. If not sure whether they are done, remove one from the oven and see if it holds its shape.	Puffs will lose their shape if removed from oven before thoroughly baked.
Make a slit in top of each puff and fill with cream filling.	

(CREAM PUFF FILLING.)

Equipment.

1 measuring cup
1 tablespoon
1 mixing bowl
1 teaspoon
1 double boiler

Materials.

¾ c. sugar
6 Tb. flour
⅛ t. salt
2 eggs
2 c. scalded milk
1 t. vanilla

Amount: Enough to fill 12 small or 9 large cream puffs.

Method.

Scald milk. Mix sugar, flour, and salt; add gradually to hot milk, stirring constantly. Cook in double boiler for 15 minutes, stirring occasionally. Beat eggs slightly. Slowly pour several tablespoons of hot mixture on to beaten eggs and stir well. Add egg mixture to thickened milk while stirring. Cook 3 to 5 minutes, or until egg yolk has thickened. Add flavouring at the last.

[*To be continued.*]

Next month's issue will deal with Miscellaneous Quick Breads and Cakes.

BELALIE (Average annual rainfall, 17.71in.).

June 19th.—Attendance, 60.

A large attendance helped to make the June meeting a success. The meeting took the form of an Exhibition of Curios and Competitions in Jams and Knitted Jumpers. Among the curios were a handsome silver samovar, an antique bronze urn, a quaint musical box that played whilst little ladies drank tea in an arbour twined with roses; a tiny pair of infant's shoes worn 70 years ago; a huge seaman's knife; a feeding bottle 80 years old; and a box made from a piece of the first mulberry tree planted in the Clare district, were all objects of interest, as was also a beaded bell rope brought from Germany in the early days of South Australia. There were exquisite examples of handwork in crocket tapestry, embroidery, and bead work, all of which were worked many years ago; whilst a handsome hooked rug and doorslips and knitted garments were examples of modern handicraft. The number of entries in the knitted jumper competition and quality of work made it difficult for the judges (Mesdames Story and Goudie, of Peterborough) to select the winners. The first prize was awarded to Mrs. K. Symonds and Mrs. A. Davies secured second honours. The prizes for best collection of jams were won by Mrs. F. Cummings first and Mrs. A. J. Symonds second (prizes donated by Branch). During the afternoon Mrs. W. Sandow, of Peterborough, gave an interesting talk on her recent trip to Fiji, and showed various native-made articles, beautiful pieces of coloured coral. and photographs and postcards. Musical items were rendered by Mrs. Hawke, Misses H. White, and A. Cummings and G. Napper. (Secretary, Mrs. E. L. Orchard.)

CLARE (Average annual rainfall, 24.56in.).

June 2nd.—Attendance, 25.

DRESSMAKING.—The subject for the afternoon was entrusted to Mrs. A. H. Rogers, who read a paper on "Dressmaking." She also had patterns, and with the aid of one of the young members, was able to show the correct way of fitting a figure. Questions on buttonholes on thick materials. reveres, fitting of sleeves, and gored skirts were some that were answered. *Making Clothes.*—Clothes are for covering, adornment, and to fulfill the demands of law. Warmth and comfort in the cold weather seem to be the greatest need, but in summer time it is even a harder matter to provide cool and suitable clothing. Appearance plays a great part in dress—all races of the world adorn themselves. Since the wearing of clothes is a necessity, so also is the making of them either by ourselves or others who have acquired the skill. There is an art in the making of clothes that fit well and are suitable to one's needs and individual style. Something can be made that is just a garment, but with care and accurate measurement the simpler articles of dress can be made quite nicely by the merest novice. Children's frocks now are almost the exact replica of their elders; they have their coats to match their frocks, and even bags of the same colour. This is a part of dressmaking that is interesting and economical, for often a piece of material that is too small for a bigger dress can be used for a child if the colour and pattern are suitable. More time and thought might be put into sewing, for there is a growing tendency to put it in the background. Some say that the factory garments are all right and cheap enough; others have let knitting obsess them—good in its place, but not instead of trying to do sewing. Beside the joy of creating, the frock is the soothing influence of the sewing and the satisfaction of saving the cost of the work. If unable to cut without a pattern, secure a simple one, see if it corresponds to the measurement required, and if not quite certain, cut another from it in newspaper, allowing the difference needed for the size. Time spent at this stage of the work is well repaid. Place the pattern on the material very

carefully and cut with turnings, allowing a good margin at the neck and armholes. If the material is at all loose, run a tacking thread round the armholes and collar line and anywhere else that is likely to pull out of shape.'' (Secretary, Mrs. McKendrick.)

HOPE FOREST AND DINGABLEDINGA.

June 7th.—Attendance, 18.

The Grape and its Uses.—Paper by Mrs. R. Wade:—''Many people do not know the food value of the grape. It is not only useful as a dessert food in its ordinary ripe stage, but can be used in many other ways. First, to obtain the dried fruit, select sound, ripe fruit, and have a dip prepared of boiling water, with addition of caustic soda, ¼lb. soda to 10 gallons of water. Immerse fruit in a wire basket for about 10 seconds, then spread on trays in the sun to dry. There are a number of other ways of using the Muscatel besides those generally used, such as making them into sauce, pickles, chutney, as well as preserving for dessert use. They can be made into vinegar, as well as grape juice—a very nice summer drink. This juice is also used to flavour invalid foods. Jam made from Muscatels and apples is very nice; the acid in the apple tones down the sweetness of the grape.

Grape Recipes.—*Grape Juice.*—Choose only sound grapes. Pick grapes from stems, and to every 15lbs. of stemmed grapes add 1 quart of water; sprinkle ¼ cup sugar (granulated sugar is best); heat slowly to boiling, boil 10 minutes to extract flavour from skins and seeds, also to sterilize the fruit. The small amount of sugar used helps to bring out the flavour while not adding material to sweeten the juice. As soon as the juice boils dip out and strain into sterilized warm bottles, filling one at a time, and cork tightly, then dip in melted wax to thoroughly seal. Can be made with any grapes except sweetwaters. *Grape Vinegar.*—To every 3lbs. of grapes picked from the bunch add 2galls. of water (previously boiled and allowed to get cool). Place in an earthenware jar in a cool place for five days, stirring morning and night, then strain through muslin. Add 1lb. sugar to 1gall. of juice. Allow to stand in earthenware jar with light cover over to keep out dust, for about six months, then strain again and bottle. Ready for use straight away. *Grape Chutney.*—1lb. grapes, ¾lb. each apples and sugar, ¼lb. sultanas, ½oz. garlic, ½ teaspoon salt, ¼ teaspoon ginger and cayenne pepper; cover with vinegar, stand over night, boil 2 hours. *Pickled Grapes.*—Boil 1 quart vinegar with 1lb. sugar, ½ teaspoon salt, 1 teaspoon cinnamon, cloves, allspice, pepper, and a little whole bruised ginger. When cool pour over grapes which have been cut off the bunch, leaving a small piece of stem on each. About 6lbs. grapes for above amount of vinegar; ready for use in about 1 month. (Secretary, Mrs. L. Fincher.)

WARRAMBOO.

June 8th.—Attendance, 12.

Ornamental Trees and Shrubs.—Paper contributed by Mrs. D. Chilman:—''Of all the various forms of gardening activities, the growing of ornamental trees and shrubs gives the most lasting pleasure and benefit, and in the long run gives the best return for the amount of labour and expense involved. In a district such as ours there are not many native trees of any beauty, and very few homes can be built among beautiful natural trees, so it becomes necessary to grow our own for shade and shelter, as well as to beautify our holdings. The various kinds of gums are the most satisfactory trees to plant in this locality, particularly the Tooart and sugar gum, being very hardy and quickly grown. These are quite easily raised from seed without any expense other than the purchase of a 6d. packet of seeds, which will give a supply of young trees for a number of years. Pepper trees, too, are a good stand-by, requiring plenty of room and protection from stock. These, too, are easily raised from seed, and do particularly well in sandy soil. The tagasaste, or tree lucerne, is a nice flowering tree, growing quickly, with graceful foliage. The various pines (such as *Insignis*, or Remarkable pine, the Aleppo, and various others), make very nice trees eventually where they survive, but are so slow growing one gets disheartened with waiting for them to show up. Sometimes the native pines can be dug up in the scrub and transplanted near the homestead at an early age, and will in time grow into very handsome trees. When planting any of the large-growing shade trees remember they are all great robbers, and to make sure they are not planted near where fruit trees, vegetables, or flowers are expected to grow. When we come to the question of shrubs, we have a very wide range from which to choose, but to keep to the more hardy varieties suitable for a dry district such as ours, the old-fashioned Oleander takes a lot of beating, doing well in almost any situation. Some of the varieties give a really wonderful show of blossoms in beautiful colourings. The Tacoma family furnishes a wide range of very ornamental shrubs, both as regards blossoms and foliage, the best known being the Scarlet-flowering *Tac. capensis.* The various species of Hybiscus, too, should do well in this climate and soil. The Pussy Willow is a shrub which has become very fashionable in recent years, and is too well known to need any comment.'' (Secretary, Mrs. M. Steer.)

MANGALO (Average annual rainfall, 14in. to 15in.).

June 13th.—Attendance, 10.

GIRLS' HOBBIES AND RECREATION.—Paper contributed by Miss H. Hannemann:—"Most girls have some special hobby or recreation which changes with the seasons of the year. There are several which one may indulge in during winter, but they are hardly suitable for summer, and *vice versa*. Knitting is fascinating for winter, and is most appropriate, for during cold weather the hands do not perspire in the handling of wools, thus spoiling the work. Usually whatever is being made is unwashable or would be considerably spoiled in washing. Many girls knit their own pullovers or cardigans of wool for winter wear, and dainty jumpers of wool and silk, or silk, in an open stitch are nice for sports wear. For ordinary knitting a good light is not so necessary as for needlework, and often it is more convenient to take it up in any spare moment. Quite a number of girls, when going to a concert, take their unfinished pullover, beret, or scarf and get quite a lot done while awaiting the commencement of the show or during the interval. There are hundreds of books of instructions on sale for knitters that may be purchased for a shilling or less. Cards with instructions for one garment only are obtainable also for a few pence. Other books describe various stitches. Being able to knit one's own jumpers makes them much cheaper, so that one can have a change more often. This season girls have been crotcheting berets and toques to match each jumper. This is very interesting. Crochet work is also done in cotton, and some very dainty d'oyleys are made. A few years ago lace edgings were very popular, but just at present there are not so many made. Tatting is more complicated. There are different designs and they make neat edges for ladies' handkerchiefs and d'oyleys. As a rule more art needlework is done during summer. A better light, good eyesight, and a steady hand and often plenty of patience are needed for this work. House linen, children's clothes, lingerie, &c., are often finished and made to look quite different with the addition of a small spray or design in the same or contrasting shade of thread. There are countless numbers of fashion journals on sale, most of which contain several free patterns, and explicit directions for cutting out, so that many girls are able to make their own frocks. This is also a saving, for often with the money which would be paid to a dressmaker for making a frock another dress length of washing or inexpensive material can be purchased. Reading is many girls' main indoor pastime. It is most educational if the right books are read, and increases a person's knowledge, especially English. Fewer girls do painting and photography where lessons can be taken. Gardening is very interesting and a healthy outdoor hobby where conditions are suitable and water plentiful. Every girl is fond of flowers and they brighten the inside as well as the outside of a home. For outdoor sports in summer tennis is undoubtedly the most healthy and popular game. Golf is a winter sport, and involves a good deal of walking. Basketball is very exciting, but a bigger number is needed to form a team. For girls, running is not such a popular sport as others, but for those who do it it keeps them fit as do all outdoor sports. Then sometimes of an evening when one is not really tired, but feeling a bit "blue," a dance is a very good remedy. A little bright music and meeting a few friends will brighten dull spirits." (Secretary, Mrs. B. Coles.)

THE JOURNAL

OF THE

Department of Agriculture

OF SOUTH AUSTRALIA.

VOL. XXXVIII. SEPTEMBER, 1934. No. 2.

Published Monthly by the Department of Agriculture.

Edited by H. C. PRITCHARD.

CONTENTS.

All communications to be addressed:

"The Editor, Journal of Agriculture, Education Building, Adelaide."

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences.

District Conferences will be held as follows:—

Fruit (Non-irrigated Districts), at Balhannah, Tuesday, November 6th, C. G. Grasby (Secretary).

The Conference will commence at 10.30. Members of Branches are invited to submit papers and questions for the agenda.

Agricultural Shows.

We have been advised by Secretaries of Agricultural Show Societies that their shows will be held as follows:—

Karoonda, Wednesday, October 3rd.
Jamestown, Wednesday, October 10th.
Loxton, Wednesday, October 10th.
Clare, Saturday, October 20th.
Burra, Wednesday, October 24th.
Minlaton, Wednesday, October 24th.
Mount Gambier, Wednesday and Thursday, October 24th and 25th.
Murray Bridge, Thursday, October 25th.
Woodside, Saturday, November 3rd.

Feeding Value of Soya Beans, Blue Lupins, and Panicum.

The Deputy Director of Agriculture (Mr. W. J. Spafford) in a reply to a correspondent says the seeds of the Soya bean have high feeding value from both the fattening point of view and the production of milk, the starch equivalent, when containing 10 per cent. of moisture, being 83.9, whilst that of peas with the same moisture content is 71.8, and the nutrient ratio of Soya beans is 1 to 1.94, against 1 to 2.81 of the peas. The growth of Soya beans can be used as green forage, stored as silage, or made into rather coarse hay, but where this plant grows strongly it is usual to use cow peas for these purposes, instead of Soya beans. They do not do well in cool, temperate climates.

Blue Lupins.—The Blue Lupin is only of value for livestock because the animals eat the seeds, but the growth is rarely touched by them. The starch equivalent of Lupin seeds, when containing 10 per cent. of moisture, is 74.3, and the nutrient ratio 1 to 2.0. The Blue Lupin has practically no value as a fodder crop. Where grown for livestock it is allowed to ripen its seeds, and when these have dropped to the ground sheep are turned on to the crop and fatten on the seed. It does not mature big crops of seed in South Australia, and so is only useful in this State as a sand-binder.

Panicum.—The seeds of Panicum are used as bird seed, but the crop is usually grown for green forage or to be converted to silage. The green forage has about the same feeding value as maize for large stock, and a slightly higher value because of finer texture for small stock and poultry.

Non-Setting of Black Prince Grapes.

Mr. G. Quinn (Chief Horticultural Instructor) advises the Secretary of the Marama Branch of the Agricultural Bureau, who reported that a 10-year-old Black Prince vine in his garden each year did not "set" its fruit, that this variety is a notoriously bad setter in the coastal vineyard areas of this State, but usually in the hotter inland districts, such as the Murray Valley and Upper North, it sets well when grown amongst other sorts. The exact cause has not been worked out, but it is evidently bound up in the matter of pollination.

It is suggested, if the owner of these Black Prince vines has another sort or sorts which bloom simultaneously with that variety, it would be worth while collecting pollen from the bunches of flowers of the other sorts—say into a glass dish and with a camel-hair brush, or a rabbit's tail—transfer it on to the flowers of the Black Prince bunches by rubbing the brush carrying the pollen up and down the bunches or inflorescences, when most of the caps have fallen from the flowers.

Potato Scab.

A subscriber to the *Journal of Agriculture* seeking information as to the best treatment for seed potatoes affected with scab, has been informed by Mr. George Quinn that two chemical treatments have been used against this disease, viz., solutions of formalin and mercuric chloride. They are applied to the seed tubers as follows:—

Formalin.—Commercial formalin (40 per cent. strength) has been used at the rate of 1lb. in 30galls of water. The tubers are placed in a loose, open-woven bag or hessian and steeped in the solution for two hours, then taken out and dried for a short time before being cut, if necessary, into sets for planting, which should be carried out without undue delay.

Mercuric Chloride (Corrosive sublimate).—This is used at the rate of 1oz. in 6galls. of water. The mercuric chloride is first dissolved in several quarts of hot water, and then made up to the above strength with cold water. A wooden vessel is desirable, as the chemical corrodes metal. The seed tubers are steeped and treated similarly to those where formalin is used.

More recent investigators prefer the mercuric chloride as a preventive of this scab, and claim greater efficiency for its use. It is a deadly poison if swallowed by animals and human beings, so that great care is essential in handling and storing it where no children or careless persons can have access to it.

Soils which are alkaline should be avoided in potato growing, as this disease is more frequently noticeable wherever fresh ashes or limestone marl has been freely mixed with the surface soil. The prevention of the attack of the disease makes for an increased yield of marketable tubers.

Sheep Blowfly.

Mr. C. T. McKenna, B.V.Sc., of the Stock and Brands Department, has supplied the following reply to a question, "What is the best method to prevent blowflies from striking sheep?" submitted at the Yeelanna Conference:—

Science Bulletin No. 40 of the New South Wales Department of Agriculture of 1933 gives the following information:—

The blowfly pest cannot be combated by any one method alone. The following methods are recommended:—

1. Crutching properly done is of proved value.
2. *Breeding.*—As the predisposition to strike in the crutch region is inherited and can be recognised (badly wrinkled about the breech), the general susceptibility of the flock may be reduced by selective breeding. It is considered that satisfactory wool quality can be retained by judicious selection.
3. *Jetting.*—This is of distinct value when undertaken immediately prior to or during a strike wave. (It is not practicable in small flocks owing to the cost of the plant).
4. *Fold Removal Operation.*—By the surgical removal of the side folds the breech is opened up, urine soiling reduced, and susceptibility to strike decreased.
5. *Dressings.*—Many dressings for treatment of struck sheep have been tried. Not one is wholly satisfactory, but the following have been found useful for routine dressing:—(*a*) 5 per cent. solution of zinc sulphate in water (approximately 1oz. of zinc sulphate to the pint of water). (*b*) 5 per cent. water solution of "Monsol." (*c*) 4 per cent. carbolic crystals in whale oil. Note.—5 per cent. water solution of copper sulphate is satisfactory except for the staining and harshness imparted to the wool.

6. *Trapping.*—The available evidence does not yet permit of a definite opinion being expressed as to the value of trapping. When trapping is practised, attention should be paid to the following:—(*a*) The trapping should be systematic, particularly prior to and during periods of strike. (*b*) Traps should be placed where sheep congregate. In hot weather they should be placed in shady situations. (*c*) If a meat bait is used, rebaiting must be frequent. (*d*) The trap should not allow the escape of any flies.

7. *Carcass Destruction.*—This is a sound sanitary procedure in the agricultural areas; carcasses should be carefully burned or buried deeply.

Publications Received.

The Library of the Department of Agriculture acknowledges the receipt of the following publications:—

"Year Book of Agriculture, 1934," U.S.A.

Annual Report, 1932, Department of Agriculture, Ontario.

Bulletins issued by Ministry of Agriculture, England:—No. 1, "Some Diseases of Farm Animals," price 2s.; No. 60, "Asparagus," price 1s.; No. 70, "Ducks and Geese," price 1s; No. 73, "Red-furred Rabbits," price 1s.; No. 75, "Poisonous Plants of the Farm," price 2s.; No. 77, "Tomatoes: Cultivation, Pests, and Diseases," price 1s. 6d.; No. 79, "Fungus and Other Diseases of Crops, 1928-1932," price 2s.

"Bulk Handling of Wheat," L. B. Mercer, M.C.E., price 1s. 6d.

"Scientific Principles of Poultry Feeding," Bulletin No. 7, price 9d. net, Ministry of Agriculture, England.

"Annual Report of the East Malling Horticultural Research Station, 1933," price 4s. net.

"Cattle and Beef Survey of the World." Report I.E.C./S.1. Imperial Economic Committee, England; price 5s. net.

"Methods of Analysis for Insecticides and Fungicides," Bulletin 82; price 3d.

"Pigkeeping," Bulletin No. 32; price 1s. 6d. (Published by Ministry of Agriculture, England.)

AGRICULTURAL INQUIRIES.

[Replies supplied by Mr. W. J. Spafford, Deputy Director of Agriculture.]

Magnesia Patches.

Yeelanna Conference: What is the best method to control magnesia patches in the soil, and what treatment is required to stimulate the growth of grass and cereals?

Reply—There are no such occurrences as magnesia patches in South Australia, but the question obviously refers to sterile patches of soil caused by an excess of common salt. The sterility of these patches is due to the concentration of soluble salts (very largely common salt) at the immediate surface of the land being so great that seeds cannot germinate, or if they do the seedlings are unable to survive for any length of time.

In the wheat-growing districts of the State it is extremely difficult to control these salt patches, because in most places it is seldom that sufficient rain falls to wash the excess of salt deep enough into the soil to permit of a good germination of seed, and unless the surface of the soil is protected from heavy evaporation by plants or some other covering the trouble will never be overcome.

Where the patches are relatively small and where plenty of farmyard manure is available, pastures can be established by ploughing the land deeply in the early winter, say 6in. to 8in. in depth, immediately covering the surface with a good layer of farmyard manure, and sowing a mixture of 6lb. of each of King Island Melilot and Wimmera Rye Grass to the acre in the manure. The resulting pasture must never be over-stocked during the first few years after establishment and stock should be removed long before the land has been bared.

It is a much more difficult problem, however, to be able to correct the trouble of excessive salt to the extent of again growing good cereal crops on the land. The concentration of salt at the surface is greatest in the autumn, and so it is unreasonable to expect wheat and oats to germinate well if sown in early winter. The salt must be lowered from the surface by ploughing the land to a depth of 6in. to 8in., being careful to turn the soil right over, covering the surface with well-rotted farmyard manure, leaving it exposed to the winter rains, and seeding with barley in early spring. If the barley fails an attempt should be made to establish Sudan Grass later on in spring. Given a wet winter, success should be attained in securing a cover for the land, but care must be exercised in not feeding the crop too severely nor in cutting it too closely, and the land should be cropped three or four years in succession to render it fit for cropping with cereals in the ordinary way.

In extreme cases of excess of salt it may be necessary to scrape from 1in. to 2in. of the surface off the affected areas at the end of March or early in April and cart it right away from the patch, before proceeding with the method of correction already described.

Drake.

Yeelanna Conference: The weed "Drake" grows abundantly around crabholes filled with water, on water-logged soil, and on new land. How does it originate?

Reply—Drake, or darnel, is one of the most persistent of the weeds which accompany the cereals, and is particularly bad in new districts, and more so where the rainfall is heavy and the soils raw than where sweet soil conditions obtain and where the rainfall is lighter. In the earlier days of wheat-growing in South Australia this weed was so bad in wheat crops that a special machine was on the market, known as a "drake screen," to remove drake seeds from the wheat before offering the grain for sale. Because of the mellowing of the soils by cultivation for crop growing, drake has been kept under in most of the older wheat-growing portions of the State, yet even in those districts it has by no means been wholly eliminated. In clayey soils or where a clay subsoil is near the surface, drake persists as a weed for a very long time because these soils take so long to become mellow, and as the weed is a water-lover it grows strongly in wet years in those locations where the cereal crops suffer because of the excessive wetness.

Drake can only develop from a seed matured by a drake plant, and although the weed is not much in evidence in the drier seasons, it is a most persistent weed and there are usually enough plants present to produce sufficient seed to foul crops in wet years. Besides this power of developing seeds on the smallest of plants, drake, like most other persistent weeds, also produces some weeds which do not germinate readily in the season they are matured, and this carry-over is generally sufficient to help account for the presence of plenty of plants in seasons favourable to their growth. When careful bare-fallowing is practised and seed wheat is properly graded, it is not usual to find many drake plants in crops, and those that are present originate from the seeds left in the ground from a previous year.

Ensilage.

Yeelanna Conference: How can stock be encouraged to eat ensilage?

Reply—There are so many cases of cattle and sheep, including some reared on stations, which have never seen silage before taking to it readily, and I have seen so few animals refuse silage of good quality, that one cannot help thinking that there is something wrong with the article being persistently refused.

If the silage is charred through being made from over-mature, rather dry forage, insufficiently weighted in stack or silo, the chances are that stock will take it fairly readily if it is sprinkled with crushed grain or bran, but if the silage is the sloppy, yellowish mass with highly objectionable odour resulting from throwing sappy growth together too quickly, it will only be taken by farm livestock in times of drought when foodstuffs are short.

Good silage should have a sweetly, nutty aroma and a pleasant slightly-acid flavour, and when of this quality most livestock eat it greedily.

Takeall Control.

Yeelanna Conference: What are the best means of controlling "takeall" so prevalent in the second and third crops of wheat grown in the Yeelanna district?

It is an incorrect agricultural practice to crop land with wheat two seasons running, and still worse to grow three wheat crops in succession, anywhere in South Australia, let alone in a district like Yeelanna, where all wheat crops are liable to attacks of "takeall" unless the greatest of care is shown. Yeelanna is a really good wheat-growing district, and good crops can be grown by all who understand the conditions and prepare against "takeall," but where this disease is so liable to occur, and can do so much damage, wheat should never follow wheat. If there is any desire to grow wheat on land not in bare fallow, it should be on grass land, and then with special soil preparation, but it would be much better for most farmers only to grow wheat on bare fallow. The principal argument used in favour of continuously cropping land with wheat, that it hastens the clearing of scrub, does not hold good in any mallee district in the State, for without exception the farmers who have farmed small areas properly without continuous cropping have cleared up their land, subdivided their holdings, and carried full flocks of sheep long before the big-area rough farmers who crop land year after year with wheat.

The only chance of growing wheat crops free from "takeall" with any degree of certainty, on land not fallowed, is to secure a good burn before preparing the land, then while the soil is still hot from the fire it should be harrowed or lightly stirred in some way. As soon after as possible it should be cultivated and then sub-packed. As the seeding of such land should be delayed as long as possible and an early variety used, a further shallow cultivation will be necessary, and the packer should again be

used, either before the drill or soon after, depending upon circumstances. A liberal application of superphosphate should be given.

Although it is possible to get good crops from wheat crops grown on land that carried wheat the previous year in a district like Yeelanna, where the climatic conditions are favorable for wheat-growing, it would be much better for all wheat-growers, and certainly of great advantage to the State, if the practice was never followed, and with very few exceptions it would be better for all concerned if wheat was only grown on land prepared as bare fallow.

Wild Oats.

Yeelanna Conference: Why is it that wild oats seed will not germinate for several seasons in some instances?

Reply—The delayed germination of some of the seeds of most of the troublesome weeds is a provision of Nature, enabling such plants to persist, and it is certainly this power which leads to the difficulty of eradicating such a weed as the wild oats, for if all seeds germinated the season following their development, such a good fodder plant would be eaten out in one year. It appears that some of the seeds of wild oats are so closely enveloped in their outer skins that sufficient moisture cannot penetrate to the kernels to lead to their germination, until the outer skins partly decay, and depending upon the conditions where the seeds lodge so the time taken to reach this stage varies and may even extend to several years.

Rust in Wheat.

Yeelanna Conference: Has any further progress been made concerning the origin of rust in crops, and what discoveries have been made to control rust?

Reply—The life history of "rust" disease of crops which does most damage in the world—the Stem Rust of Wheat—has been thoroughly understood for generations in most wheat-growing countries, but there is a hiatus yet to be definitely filled in the life-history of the Australian form. The stage between the wintering spores and the uredospores which are first developed in the spring is yet to be discovered, but once uredospores are produced it appears that wind blows them about to be a source of infection wherever they may lodge.

The world over, pathologists and plant breeders are working towards the control of Stem Rust of Wheat, and the bulk of their activities are in the direction of the production of heavy-yielding varieties resistant to the disease. No great trouble has been experienced in obtaining disease-resistant crossbreds between the bread wheats and durum wheats, and between bread wheats and emmers, but securing this resistance combined with the power of producing heavy grain yields is very difficult. In the United States of America some rust-resistant crossbreds between Marquis and emmer now being distributed with confidence that they will yield well, but these particular kinds are not at all promising in Australia as field crops. One of these American crossbred wheats, "Hope" by name, is giving very encouraging results as a parent of rust-resistant wheats in New South Wales, and at present it appears that some of the apparently heavy-yielding crossbreds have high rust-resistance and more should be heard of them in the near future.

Cropping Sandhills.

Kyancutta Conference: Are the sandhills of the Warramboo district worth cultivating and sowing for wheat?

Reply—In very few mallee districts of South Australia are the sandhills capable of frequently producing payable crops of wheat, and with the average annual rainfall as low as that of the Warramboo district, good results can hardly be expected from wheat crops unless the land is rested from cropping and left to produce pasture for relatively long periods between crops. Where the sandhills do not form an excessively high

proportion of the holding, the scrub should not be removed from the ridges and although the protection of the scrub leads to some inconvenience in the early days of settlement, the final result makes it worth while. After the scrub has been cleared from the sandy portions of holdings, the aim should be to crop seldom and carry as many head of stock as possible. This can only be done by growing some fodder crops for a few years in succession and then producing a crop of wheat. Lucerne will do fairly well on such sandy land, and if the pasture is maintained for about four years a good crop of wheat could be grown before again seeding down to lucerne. Failing lucerne, cereals such as oats, rye, or barley, or mixtures of any or all of them, could be sown in the autumn of each of three or four years in succession, to be grazed down by livestock and then the land could be cropped with wheat.

If lucerne is adopted as the grazing crop, 4lb. or 5lb. of seed mixed with 1cwt. of superphosphate should be drilled in to the acre in the autumn or winter with a disc drill in the stubble of the wheat crop without previous cultivation. Whole fields should be sown to lucerne, or the portions of fields seeded to the crop should be fenced off, as it is impossible to properly establish lucerne on part of a field unless the remainder of the field is seeded to a grazing crop which grows at the same time as the lucerne, and at present such a crop is not known for the Warramboo district.

Other than lucerne the only pasture plant which can be grown with any degree of certainty is Wimmera Rye Grass, and it can be established by seeding 2lb. of seed per acre in a cereal crop that is to be harvested for grain. The seed would be mixed with the superphosphate in the manure-box of the seed drill. After three or four years of Wimmera Rye Grass the land can again be cropped for one season, and then rested under pasture for a few more years before being put under wheat again.

HORTICULTURAL INQUIRIES.

[Replies supplied by Mr. G. Quinn, Chief Horticultural Instructor.]

Fruit Trees for Central Eyre's Peninsula.

Kyancutta Conference: The best variety of fruit trees for Central Eyre's Peninsula?

Reply—From experience gained in the orchard at Minnipa Experiment Farm, the following kinds of fruits appear best suited:—Apricots—Newcastle Early, Oullin's Early, and Moorpark; almonds—Preferably hardshells on account of parrot pest; figs—Early ripening sorts, such as White Genoa and Black Ischia; peaches—Suggest early midseason sorts, such as Wright's Early, Elberta, Louis Grognet; pears—Clapp's Favourite, Packham's Triumph; grape vines—Green's Early, Golden Chasselas, Sweetwater, Red Malaga, Red Frontignac, Black Muscat Hamburg, Black Prince; orange—Washington Navel, Siletta; mandarin—Dancy's Tangierine; lemons—Lisbon Improved. Whilst all trees would benefit from irrigation, it is quite essential for the oranges and lemons.

A member of the Kyancutta Branch stated that he had grown Mountain Rose peach, Muscatel, and Red Malaga vines with success. He said that early varieties of fruit trees appeared to grow better than later varieties.

White Ants Attacking Fruit Trees.

Kyancutta Conference: What is the best plan to prevent white ants from attacking fruit trees?

The following reply is taken from page 156 of the September, 1931, issue of the *Journal*:—Termites usually find an entry *via* a dead area, such as is left where roots have been broken or cut away when planting, or where the spade, hoe, or fork has damaged and exposed the wood near the soil line when digging or working around the trees after they are planted.

Undoubtedly, the best method of circumventing these pests would be found in sowing the stones of almond, peach, or apricot on the spot where the trees are to be grown, and budding them on the spot well up the stem away from the ground. This avoids the broken root danger.

Mr. Quinn planned this type of propagation in the orchard at the Minnipa Experiment Farm, but the absence of a skilled orchardist in the first years spoilt the experiment, as the efforts at budding were not made at the right stage of growth of the seedlings, and the wounds ultimately made on the rootlings when beheaded were too large, and not sufficiently protected to secure a rapid healing over of the injured tissue.

As a good percentage of seedling peach, apricot, and almond trees produce quite good fruit—though not necesarily resembling the fruits of the parent tree—it might be worth while, under the circumstances, growing some seedlings, even if they are never budded or grafted to known kinds. If this is tried, make holes as if to plant a tree, and after filling them up, place a stake in the middle of each and plant three fruit stones around each stake. If they all grow and become established, the surplus can be pulled out a year later.

In preparing holes for fruit trees with animal manures as a fertiliser, do not use much manure in each hole, and what is used should be thoroughly mixed throughout the lower or subsoil. For instance, open a hole 3ft. square, taking off the first spade depth. Then break the subsoil for about a foot deep with a pick or crowbar and do not remove this soil, but mix about half a small barrowful of the manure very thoroughly with it, and then fill in some of the top soil before planting the tree on a central mound. Do not place the roots in direct contact with this added manure, but place it where the new roots must search for it.

There is nothing known to Mr. Quinn that can be painted on to the bark or stems or roots which will prevent or kill termites without also injuring or killing the trees, but dead scars may be coated with tar or even arsenic solution. If, when planting, any roots are found to be broken or in need of reduction, a dab of tar could be placed over the cut end.

An idea worth trying would be to take some stakes—soft wood of something favoured by termites—and soak them in a solution of arsenic before burying or driving them into the ground around the tree. These would act as permanent poison baits for the termites.

Arsenic solution could be made by boiling about 4oz. of white arsenic and 8ozs. of washing soda in a couple of gallons of water in a petrol tin until all is dissolved—about 20 minutes. Then fill the tin up for steeping the stakes. Care must be taken in handling and boiling arsenic—do it outdoors if possible—and the tin must not be afterwards used for any other purpose or the solution left where children or animals may reach it.

A mulch of stable manure spread on the surface above the root spread about October would prove valuable in keeping the soil cooler and moister during the summer months.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

"Hamilton" reports pig sties infested with fleas.

Reply—It is very difficult—often by any special treatment—to eradicate fleas from any premises which they infest, and if left to themselves they will often ultimately disappear just as suddenly as they came. It would be advisable to leave the sties empty of stock for a time and house the pigs away in fresh temporary premises. All litter, &c., should be removed and burnt and the sties thoroughly cleaned out and disinfected. Subsequently occasional lime-washing with a pint of kerosene added to each gallon of wash will prove helpful.

"Tintinara" asks for (1) *Strength and dose of bluestone drench for sheep, and* (2) *Suitable lick for sheep and cattle.*

Reply—The following are the particulars:—Copper sulphate (bluestone), 1lb.; water, 6galls. Use only fresh crystals of bluestone and use glass or earthenware containers. Dissolve the bluestone in ½gall. to 1gall. of boiling water and then add cold water to make total quantity up to 6galls. If desired, 13½ fluid ozs. of nicotine sulphate (Black Leaf 40) may be added to the above amount of bluestone solution. This increases the efficacy of the dronch, particularly against tapeworms. Doses to be given:—Adult sheep, 2 fluid ozs.; two-tooths, 1½ fluid ozs.; lambs (6 to 12 months), 1 fluid oz.; lambs (2 to 6 months), ½ fluid oz. (1 tablespoonful equals ½ fluid oz.).

(2) Suitable licks are either of the following:—1. Dicalcic phosphate, 50 parts; coarse salt, 50 parts; molasses added up to 10 per cent. 2. Sterilized sweet ground bonemeal, 60 parts; coarse salt, 40 parts.

"Truro" reports (1) *Death of four cows; loss of milk, stiff in front legs, tongue swollen with slobbering, off feed.* (2) *Horses continually stamping feet, which are very scaly.*

Replies—(1) The cattle died from botulism (dry bible). The toxin (poison) which causes this disease is usually obtained from contaminated bones or carcasses of dead animals (including rabbits), which cattle frequently chew during the dry period of the year in their search for mineral matter. The bones or carcasses become contaminated by germs invading them and manufacturing the poison or toxin in surroundings which the germ likes. The disease is usually fatal. The only treatment which could be tried is to give a teaspoonful of powdered nux vomica three times daily for five days. (Mix the powder with treacle and smear well back on the tongue.) Drenching is not advised, as frequently the animal cannot swallow. Occasionally cows can contract the

disease by taking the toxin in the feed. In this case the feed (chaff) has been contaminated by mice which serve as the animal matter (in place of bones or carcasses) in which the germs can manufacture the poison. Again, dam water may contain the toxin by coming in contact with affected carcasses.

(2) It is suggested that the legs be washed with warm lysol solution (1½ teaspoonfuls to the pint) once daily for three to four days. An old scrubbing brush is useful. Subsequently apply the following lotion daily:—Creosote, 1 part; turpentine, 6 parts; raw linseed oil, 20 parts.

"Clarendon" has a foal with a navel rupture.

Reply—The presence of a hernia (rupture) is dangerous in proportion to its size. A small one may not interfere with the health of the animal and may disappear before the animal is twelve months old. If large, an operation is required owing to the danger of portion of the gut being caught in it and strangulated. If the swelling is only 2in. or 3in. in diameter, it is suggested that a blister, such as red iodide of mercury —strength 1 in 8 of lard—be applied once or twice with a ten-day interval in order to cause swelling of the skin, which will tend to push the contents of the sac into the belly.

"Milang" reports two ewes which have gone completely blind.

Reply—The conditions described point to the disease being due to a toxaemia (poisoning), which often occurs in pregnant ewes, especially those carrying twin lambs and within the last month of pregnancy. The treatment indicated is to administer twice a day for three or four days (by smearing on the tongue) 2 tablespoons of molasses. From a chemist procure the following powders:—Take fused calcium chloride, 1 dram; one powder—obtain eight. One powder to be dissolved in a half-cup of water and given as a drench twice a day. Affected sheep should be given plenty of exercise if in fat condition.

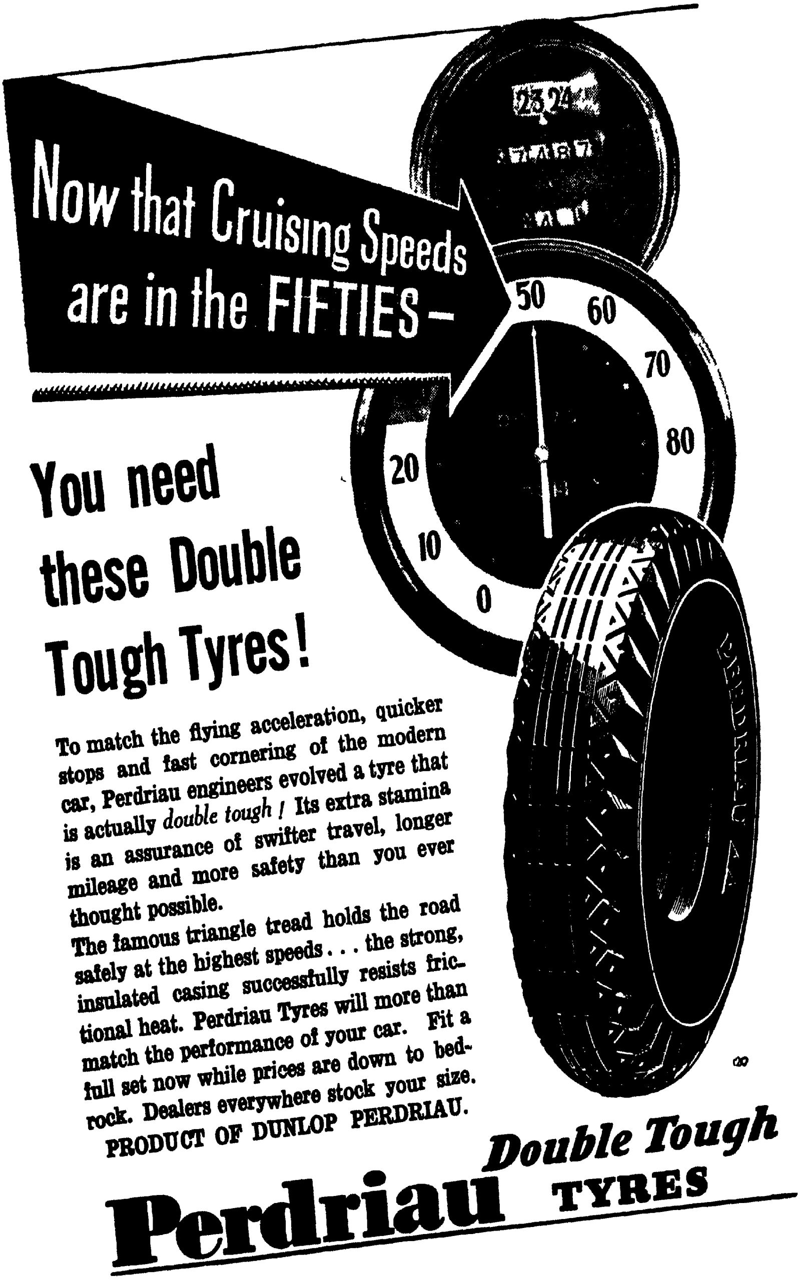
Blackheath Agricultural Bureau reports colt foal kicked on stifle joint 18 *months ago. A knocking noise can be heard when the horse trots.*

Reply—It is possible that the condition is a luxation (slipping out) of the patella (kneecap). As the condition is a chronic one, recovery is very doubtful. Try the effects of a blister (biniodide of mercury 1 in 8; you could get a small chip box full from nearest chemist). To use, clip hair from over kneecap. Wash thoroughly with warm water and soap to remove dirt and grease. Dry and rub in the blister over the area for 10 minutes at least. Subsequently tie up the foal short until next day so that it does not muzzle the part. Wash blister off next day and rub in olive oil. Repeat blistering if necessary in six weeks.

"Morchard" asks (1) *Cause of black spots on Merino lambs; and* (2) *Cause of "white eye" in cattle similar to pink eye in sheep.*

Replies—(1) The occurrence of the black spots or patches is an example of what is termed "reversion" or "throwing or breeding back," and they are merely due to the outcropping of a latent genetic or hereditary factor received from the ancestry of the animals. Such a latent factor as this may be transmitted through several generations before making its reappearance, and it does not necessarily imply that the animals are not "pure bred." It is a reminder that the remote ancestry of our present-day sheep had this fault and its now only occasional reappearance is due to attempts that have since been made by breeders to eliminate it.

(2) This is a contagious keratitis or inflammation of the cornea (interior surface of the eye). The condition at times occurs through unknown causes, but it may also originate from injury of some kind (such as scratches or pricks) to the cornea, or through an extension of an inflammation of the conjunctiva, or inner surface of the eyelids. The trouble very often clears up after a time without any treatment, and again, despite every treatment, it may become worse and worse and result in permanent loss of sight. A 1 per cent. solution of silver nitrate applied to the affected eyes three or four times daily is useful treatment; also a 2 to 3 per cent. ointment of yellow oxide of mercury, some of which should be placed on the inside of the eyelids twice daily.



Now that Cruising Speeds are in the FIFTIES –
You need these Double Tough Tyres!
To match the flying acceleration, quicker stops and fast cornering of the modern car, Perdriau engineers evolved a tyre that is actually *double tough!* Its extra stamina is an assurance of swifter travel, longer mileage and more safety than you ever thought possible.
The famous triangle tread holds the road safely at the highest speeds . . . the strong, insulated casing successfully resists frictional heat. Perdriau Tyres will more than match the performance of your car. Fit a full set now while prices are down to bedrock. Dealers everywhere stock your size.

POTATO EXPERIMENTS AT JERVOIS.

[By R. C. Scott, Supervisor of Experimental Work.]

Consequent upon the low prices which dairy produce has recently commanded in South Australia a number of settlers on the reclaimed swamp areas of the lower Murray have been testing different crops in the effort to discover something which will yield profitable returns and ease the position in which they are placed.

Included in such crops are potatoes, and in order to provide information relative to the possibility of their successful cultivation a series of experiments were commenced in 1932 on the property of Mr. J. W. E. Schultz, at Jervois. In this connection it was considered advisable to conduct investigations not only regarding the cultivation of the crop but also to test the keeping and cooking qualities of the tubers harvested. The latter experiments were included because it has been frequently stated that potatoes marketed from the swamp areas will neither keep well nor provide foodstuff of pleasant flavour or good mash when cooked. As far as the tests regarding cooking qualities are concerned the Domestic Arts section of the Education Department very kindly co-operated in the work, and this line of investigation was carried out by Miss Ellie Campbell, Inspector of Domestic Arts.

However, before proceeding to a discussion of the results obtained an examination of the statistics concerning potatoes in this State will be of interest.

In the following Table particulars concerning this crop for the ten-year period 1924-33 are set out:—

Potatoes in South Australia, Seasons 1924-33.

Year.	Area.	Total Yield.	Acre Yield.	Average Price. Mount Gambier.	Average Price. Other.	Imports. Bags.	Imports. Tons. (Approx.)	Total Requirements.
	Acres.	Tons.	Tons.	£ s. d.	£ s. d.			Tons.

The figures showing the quantities of potatoes imported into South Australia have been extracted from the records of the Plant and Fruit Inspection Officers. The returns supplied show potatoes in numbers of bags, and an allowance of 16 bags to the ton has been made in order to convert the figures to a tonnage basis.

Included in the imports are the weights of tubers imported from other States, chiefly Victoria, for use as seed and this quantity probably represents about 2,000 tons per annum. It will be noted that in the preceding table the average price is quoted under two sections, namely, that for Mount Gambier potatoes, which includes those harvested in the South-Eastern districts generally, and that for potatoes secured from other areas in the State.

Considerable variation occurs from year to year but the value is consistently in favour of crops produced in the latter areas. As far as can be ascertained this difference is not regularly associated with any variation in quality, although in the present season the Mount Gambier potatoes are slightly inferior to those from the Adelaide Hills, but appears to be associated with damage caused by transport and the ability of growers situated close to the market to take advantage of any fluctuation in price that may occur.

Over the ten-year period the mean total requirement for potatoes in South Australia has been 26,077 tons per annum. The average yield is 3.80 tons per acre and on this basis a normal crop from 6,862 acres would fully supply the local demand for potatoes. As the acreage planted has steadily increased from 2,895 acres in 1925-26 to 6,454 acres in 1932-33, with a possible further increase for 1933-34, figures for which are not yet available, it would appear that we are approaching the limit for area of crop planted.

Potato Experimental Plots at Jervois.

On the other hand, the season just passed has proved very unsuitable for the development of good potato crops and in consequence instead of the local market being flooded 6,102 tons of potatoes have had to be imported during the 12 months ending June 30th, 1934. Further, the mean acre yield of only 3.80 tons indicates that considerable areas of land now planted are not well suited to the production of potatoes. Consequently, whilst it is not desirable that any appreciable increase in total acreage should occur there is evidence that considerable areas now utilised for this crop could with advantage to all concerned be better employed in producing other agricultural produce leaving an opening for planting additional land in districts where large crops of improved quality tubers can be regularly harvested.

Therefore, if it can be demonstrated that high yields for quality potatoes can be obtained from the reclaimed swamp lands there is room for expansion in this direction, but as an average crop from approximately 7,000 acres will supply the requirements of the State and the area planted in 1933-34 approaches this figure, such expansion must result in the squeezing out of growers situated in districts of irregular climatic conditions or those on relatively unsuitable soils.

There is another point which must be strongly emphasised, namely, that if additional planting is attempted the quality of the potatoes marketed must be above the general average of those offered to-day. In the absence of any Government certification scheme the grower must be his own inspector and be prepared

to build up a reputation as a man who regularly submits a uniform and reliable grade of potatoes. In this way the confidence of buyers will be commanded with consequent benefit to the producer.

The number of grades into which the tubers should be separated would depend upon the requirements of the trade, but without fail, all damaged, diseased, or inferior potatoes should be consistently excluded.

The position therefore, appears to be that if only average yields can be anticipated and no improvement in quality attempted, planting has practically reached the limit in this State but at the same time profitable expansion can occur if the crop is seeded under the following conditions:—

1. A climate which is regularly favourable or when irrigation water is available.

2. The soil type and cultivation methods are such that given adequate soil moisture and freedom from disease, yields at least approaching double those shown as the average for the State can be expected.

3. The grower is prepared to grade his crop carefully and only market clean sound tubers.

Unless such requirements can be complied with growers should not aim at any increase in area but on the other hand should seriously consider a curtailment of their operations. Therefore, when examining the results from the Jervois experiments and considering the possibilities of potato growing in these areas the foregoing facts must be kept clearly in mind.

MANURIAL EXPERIMENTS.

The area included in the experiment totalled approximately 3 acres in 1932 and 4 acres in 1933. In the former year two varieties, namely, Carmen and Up-to-date were seeded whilst in the latter season Carmen only was planted and each manurial dressing replicated four times.

The land was broken up in July and after good preparatory tillage seeding took place in early December. A few days prior to planting the block was irrigated.

The plan of experiment and the results obtained are shown in the following table:—

Manure.	Yield per Acre. 1932.			1933.			Mean.			Gross Value.			Nett Value.		
	Tons	cwt.	lbs.	Tons	cwt.	lbs.	Tons	cwt.	lbs.	£	s.	d.	£	s.	d.
No manure	8	4	57	6	5	19	7	4	94	36	4	2	36	4	2
3cwts. Superphosphate	8	12	106	6	5	18	7	9	6	37	5	3	36	10	3
3cwts. Superphosphate, 1cwt. Sulphate of Ammonia	—			6	9	37	—			—			—		
3cwts. Superphosphate, 2cwts. Sulphate of Ammonia	8	12	8	6	9	38	7	10	79	37	12	9	35	11	9
3cwts. Superphosphate, 1cwt. Sulphate of Ammonia, 1cwt. Sulphate of Potash	9	9	101	6	12	93	8	1	42	40	6	11	37	17	11
6cwts. Superphosphate	9	5	21	6	12	72	7	13	103	38	9	7	36	19	7
6cwts. Superphosphate, 1cwt. Sulphate of Ammonia	8	15	92	6	16	0	7	15	102	38	19	7	36	16	7
6cwts. Superphosphate, 2cwts. Sulphate of Ammonia	9	13	2	6	15	93	8	4	48	41	2	2	38	6	2
6cwts. Superphosphate, 1cwt. Sulphate of Ammonia, 1cwt. Sulphate of Postash	9	1	92	6	19	37	8	0	65	40	2	11	36	18	11

In calculating the value of the crop the following prices have been allowed:—

Potatoes, £5 per ton.
Superphosphate, 5s. per cwt.
Sulphate of Ammonia, 13s. per cwt.
Sulphate of Potash, 21s. per cwt.

Owing to an irregularity no yields were available from the plot dressed with 3cwts. of superphosphate and 1cwt. of sulphate of ammonia in 1932, and in order to safeguard against difficulties of this nature arrangements were made for seeding the plots in four replications in the following year.

In considering the above yields it should be noted that they represent the weights of sound marketable tubers and do not include inferior, damaged, or diseased potatoes. In this connection it is estimated that an average of two tons per acre had to be discarded in 1933. These rejects naturally have a certain value, particularly in a short year, but in some seasons are difficult to dispose of at any price.

The yields harvested from the different plots fluctuate considerably, although in both years an increased return has followed the application of fertiliser. In 1933 there was a slight addition in yield when 1cwt. of sulphate of potash was added to the superphosphate and sulphate of ammonia dressing, in each case being approximately 3½cwts. per acre.

Examination of the mean yields over the two seasons shows the maximum return, namely, 8 tons 4cwts. 48lbs., to have been dug from the area receiving 6cwts. of superphosphate and 2cwts. of sulphate of ammonia. As the no manure-plot returned 7 tons 4cwt. 94lbs., the increase due to the manuring is slightly more than 1 ton of potatoes per acre. The next highest yield is 8 tons 1cwt. 42lbs., from 3cwt. of superphosphate, 1cwt. of sulphate of ammonia, and 1cwt. of sulphate of potash plot, followed by 8 tons 0cwts. 65lbs., from the area receiving an additional 3cwts. of superphosphate, making 6cwts. of this fertiliser, together with 1cwt. each of sulphate of potash and sulphate of ammonia.

After money allowances have been made for the fertiliser and potatoes a nett return of £38 6s. 2d. per annum is shown for the 6cwts. of superphosphate and 2cwts. of sulphate of ammonia plot, or £2 2s. more than that from the no-manure plot. On the records obtained this is the most profitable manuring. However, the yields tabulated are inconclusive and except for the nett value mentioned, together with that for the 3cwt. superphosphate, 1cwt. sulphate of ammonia, and 1cwt. sulphate of potash application, the remainder are not appreciably greater than that from the no-manure plot.

Consequently, no definite recommendations can be made, but it is proposed to continue the experiment in future years and endeavour to reach some finality regarding the manuring of potatoes in these areas.

KEEPING QUALITIES.

In order to ascertain whether potatoes raised under these conditions could be stored satisfactorily and also the effect, if any, of the various manurial treatments on the keeping qualities, one bag was selected at random from the number harvested from each plot. In addition four bags of commercial potatoes were purchased, two of which originated from the Adelaide Hills and two from the South-Eastern district. The tubers thus obtained were stored in the Agricultural Pavilion at the Adelaide Show Grounds. They were placed on wooden shelves with

a good bed of straw beneath the potatoes and a thick layer on top. This occurred during the first week of June and the potatoes were allowed to remain until October 20th, when the percentage of waste was determined. By this time practically all the tubers had begun to shoot and were inclined to be shrivelled. Any exhibiting signs of decay were set aside and weighed, and it was surprising to note how few had deteriorated to this extent.

The actual figures were 0.8 per cent. decay for the Jervois potatoes and 1.8 per cent. for the remainder. However, the latter figure was influenced by a relatively high storage loss on one bag of Mount Gambier potatoes which possibly were more or less damaged in the rail journey to Adelaide. As far as the effect of the various manurial dressings is concerned no appreciable difference could be attributed to any alteration in this respect as the decay in those harvested from the no-manure plot was practically the same as that recorded for those from the area receiving the maximum quantity of fertiliser.

The results obtained therefore indicate that potatoes raised on the Murray Swamp lands possess quite satisfactory keeping qualities and are quite equal to the average commercial potato in this respect.

However, in this connection emphasis should be placed on the fact that all tubers were perfectly sound at the time of putting down. No potatoes that were damaged in harvesting or in any other manner were stored with the result that their liablity to remain in a sound condition was not affected by outside agency. Consequently, from the results obtained the assertion that potatoes raised on the reclaimed land of the Lower Murray will not keep satisfactorily appears to be without foundation.

COOKING QUALITIES.

There is no way of ascertaining the relative quality of flavour, flouriness, and other characteristics of a potato which go to make it an attractive foodstuff for human consumption without making an actual test and examination of the cooked tuber. Consequently, we are indebted to the Education Department and Miss Ellie Campbell, Inspector of Domestic Arts, in particular, for undertaking the necessary tests.

The report of Miss Campbell is as follows:—

"The tests were carried out at the Norwood Central Domestic Arts Centre.

Three methods of cooking were employed in the tests:—

(*a*) Steamed in order to ascertain the flavour unaffected by hot fat or boiling water.

(*b*) Boiled, as the most universal method of cooking potatoes and to obtain the quality of the mash.

(*c*) Baked, as another popular method of cooking this vegetable.

The following points were considered:—

1. *The Size.*—A potato of 3ozs. weight was considered the most desirable size. If the potato could be cooked and served as a whole, which is desirable, or if it would be necessary to divide the potato before cooking. The cutting of a potato into sections before cooking is undesirable for it exposes a greater surface from which the mineral salts could be dissolved, thus decreasing the food value of the vegetable. Also it was ascertained that a potato cut into sections absorbed 2ozs. weight of water whilst boiling.

2. *The Eyes.*—If the eyes were deep and required much cutting to remove them, which would cause waste. If there were few or many eyes which would materially affect the time in preparing the vegetable and the amount of waste.

3. *The Colour and Appearance when Cooked.*

4. *The Texture.*

5. *The Flouriness.*

6. *The Flavour.*

7. *The Mash.*—(Only boiled potatoes were mashed).

Points 1 and 2 give the economic value from the housewife's point of view. Ten marks were allowed for each section."

The key to the test numbers used in the following tables is as follows:—

Test No.	Variety.	Manure Per Acre.
1	Up-to-date	No Manure
2	Up-to-date	3cwts. Superphosphate
3	Up-to-date	3cwts. Superphosphate 1cwt. Sulphate of Ammonia
4	Up-to-date	3cwts. Superphosphate 2cwts. Sulphate of Ammonia
5	Up-to-date	3cwts. Superphosphate 1cwt. Sulphate of Ammonia 1cwt. Sulphate of Potash
6	Up-to-date	6cwts. Superphosphate 1cwt. Sulphate of Ammonia
7	Up-to-date	6cwts. Superphosphate 2cwts. Sulphate of Ammonia
8	Up-to-date	6cwts. Superphosphate 1cwt. Sulphate of Ammonia 1cwt. Sulphate of Potash
9	Carmen	3cwts. Superphosphate
10	Carmen	3cwts. Superphosphate 1cwt. Sulphate of Ammonia
11	Carmen	3cwts. Superphosphate 1cwt. Sulphate of Ammonia 1cwt. Sulphate of Potash
12	Carmen	6cwts. Superphosphate
13	Carmen	6cwts. Superphosphate 1cwt. Sulphate of Ammonia
14	Carmen	6cwts. Superphosphate 2cwts. Sulphate of Ammonia
15	Carmen	6cwts. Superphosphate 1cwt. Sulphate of Ammonia 1cwt. Sulphate of Potash
16	Carmen (Victorian Seed)	No Manure
17	Carmen (Victorian Seed)	3cwts. Superphosphate 2cwts. Sulphate of Ammonia
18	Up-to-date (Commercial)—Adelaide Hills	—
19	Up-to-date (Commercial)—South-East	—
20	Carmen (Commercial)—Adelaide Hills	—
21	Carmen (Commercial)—South-East	—

20	7·0	8·9	15·9
21	9·8	9·6	19·4
Mean for Commercial Potatoes	8·9	8·5	16·4

In the matter of size the swamp potatoes are placed at a disadvantage, but it should be recalled that the average yield was over 8 tons per acre, and consequently the tubers developed to full dimensions.

On the other hand large potatoes are not always regarded with disfavour as they are much easier and quicker to prepare and therefore where large quantities have to be handled, such as in cafes, hotels, &c., their use results in a saving of labour. However, in the above table they have been viewed from the point of view of food value and the loss attendant with cutting.

From this aspect the mean for commercial potatoes is 16.4 points and that from the Jervois potatoes 13.2 points. So far as the two varieties are concerned there is very little to choose between them as they are both of relatively flat oval shape with similar characteristics regarding size and eyes. Very little can be said in connection with the influence of the different manurings as there is no regularity in the variations that have occurred. So much depends upon the fair average quality of the samples submitted for examination that unless a large number of potatoes are included in each, comparative figures would not be obtainable. However, from the tests made it would appear that potatoes harvested from the Murray Swamps are rather larger and with eyes a little deeper than the average South Australian sample, but these facts are not particularly important.

TABLE SHOWING COOKING QUALITIES.

Test No.	Colour and Appearance.	Texture.	Flouriness.	Flavour.	Mash.	Total. points.
	Max. points 10.	Max. points 10.	Max. points 10.	Max. points 10.	Max. points 10.	50
1	4 Yellowish on outside, but white in centre. Retains shape when baked but breaks when boiled	3 Solid. $\frac{1}{4}$in. from outside a dark fibrous	4 Better when steamed	5 Fair	1 Not fluffy, but heavy	17
2	4 Discoloured in parts, especially at eyes. Outer part very broken	5 Dark fibrous lines radiating to centre. Otherwise good	5 Outer layer very fair	6 Very fair	3·5 Smooth, but inclined to be solid	23·5
3	7 Even creamy colour. Retains shape but does not look dry	8 Firm, only a thin fibrous layer $\frac{1}{8}$in.	6 Very fair	6 Strong	7 Dry and smooth	34
4	3 Yellowish	4 Fibrous threads all through	6·5 Very fair	3 Poor	6 Dry, but not fluffy	22·5
5	6 Deep creamy colour. Better steamed or baked	8·9 Fine texture in centre	9 Good	9 Very pleasant	6·4 Very fair	39·3
6	3·8 Poor colour, dark and waxy	3·7 Fibrous layer $\frac{1}{4}$in. Centre solid	3 Poor	1 Poor	3 Lumpy	14·5

8	7 Even, yellow throughout	6 Breaks easily, fibrous threads all through	8·6 Fluffy, good	3 Poor	8 Good, but fibrous	32·6
9	8 Clear, even creamy. Retains shape	5 Fibrous all through	5 Fair	3 Poor	2·6 Poor	23·6
10	4·2 Yellowish, uneven. Outer layer breaks away	4 Firm, fibrous to centre	3 Poor	4 Best baked. Otherwise poor	4 Poor	19·2

TABLE SHOWING COOKING QUALITIES—CONTINUED.

Test No.	Colour and Appearance.	Texture.	Flouriness.	Flavour.	Mash.	Total.
	Max. points 10.	Max. points 10.	Max points 10.	Max points 10.	Max. points 10.	50
11	4·2 Dull. Uneven. Does not retain shape	4·8 Firm, with fibrous threads throughout	5 Fair	5·6-Very fair	4·5 Fair	24·1
12	9 Cream throughout. Retains shape	7 Very even. Fine but fibrous	6 Very fair	3 Strong, unpleasant	5 Fair	30
13	9·6 Even pale cream. Retains shape	6 Two distinct rings of fibrous threads	8·6 Good	7 Pleasant	6 Very fair	37·2
14	5 Some samples good colour, others poor	9 Fine and even	9·6 Good	5 Strong	8·9 Good	37·5
15	7·8 Dull in centre. Retains shape	5 Fairly fine	7·5 Very fair	8·5 Pleasant	8 Good	36·8
16	4·5 Discoloured on outside. Firm and waxy	5 Outer layer very fibrous	2·8 Poor	8 Sweet and pleasant	6 Fair	26·3
17	7 Clear even white. Breaks easily	8·6 Very fibrous when large. Smaller potatoes, fine even grains	9·2 Good	8 Good	9·4 Smooth, fine	42·2
18	4·5 Dark all through. Retains shape	4 Very firm outer layer	5 Fair	5·4 Very fair	6 Dry, but fibrous	24·9
19	7·2 Deep cream, even. Retains shape	6 Even close grain. Hollow in centre when cooked	4 Poor	4·5 Fair	4·6 Fair	26·3
20	9·8 Clear white ; few dark patches. Retains shape	9·6 Even, close. Breaks easily	9·3 Good but not fluffy	10 Very pleasant	9·7 Dry and smooth	48·4
21	8 Several very dark patches. Retains shape	8·5 Outer layer very firm	7·4 Very fair	8·2 Pleasant	9 Dry and white	41·1

In the above Table the cooking qualities of the potatoes from the varous plots have been shown comparatively with those of potatoes regularly available on the Adelaide market.

Unfortunately, the raw appearance of a potato does not always indicate its value for human consumption since this is connected with the appearance, the flavour, and the consistency of the cooked article. A good potato must yield an even creamy floury crystalline mass which is of pleasant flavour.

These requirements are dependent upon various factors as for example an abundance of starch tends to encourage flouriness whilst if the proportion is small the potato will be watery and soggy when cooked. Again, a sufficiency of protein which hardens on cooking allows for the formation of a framework which holds the starch lightly together so that the potatoes retain their shape, giving them a crystalline attractive appearance. In addition, the flavour will vary according to the variety, soil, and other conditions but in all cases it is essential that it be full and pleasant. Some potatoes are slightly acid, others again are inclined towards sweetness, whilst green-ness, due to exposure or the formation of sprouts, causes the development of unpleasant flavours.

Because of these facts it was necessary to carry out cooking tests in the effort to determine how potatoes produced, under such conditions, compared with those offering in Adelaide and also to endeavour to ascertain whether any variation in manuring would have influence in this direction.

Considering the tests first of all from the point of view of the variety, that is to say, tests No. 18 and 19, representing Up-to-Date variety, and Nos. 20 and 21, Carmen variety, secured from the Adelaide Hills and South-Eastern districts in each instance, it would rather appear that Carmen offers superior cooking qualities. In this respect the Carmen from the Adelaide Hills was almost perfect and Miss Campbell awarded it 48.4 marks out of a maximum of 50.

In the case of the manurial trials the tests were replicated in practically all instances, and therefore in the following table the results obtained from each replication together with those for the commercial potatoes have been averaged:—

Test No.	Manure Per Acre.	Colour and Appearance.	Texture.	Flouriness.	Flavour.	Mash.	Total.
	Maximum—	20	20	20	20	20	100
1 & 16 ...	No Manure	8·5	8·0	6·8	13·0	7·0	43·3
2 & 9	3cwts. Superphosphate......	12·0	10·0	10·0	9·0	6·1	47·1
3 & 10 ...	3cwts. Superphosphate...... 1cwt. Sulphate of Ammonia .	11·2	12·0	9·0	10·0	11·0	53·2
4 & 17 ...	3cwts. Superphosphate...... 2cwts. Sulphate Ammonia ..	10·0	12·6	15·7	11·0	15·4	64·7
5 & 11 ...	3cwts Superphosphate ...... 1cwt. Sulphate Ammonia.... 1cwt. Sulphate Potash	10·2	13·7	14·0	14·6	10·9	63·4
12	6cwt. Superphosphate	18·0	14·0	12·0	6·0	10·0	60·0
6 & 13 ...	6cwt. Superphosphate ...... 1cwt. Sulphate Ammonia ...	13·4	9·7	11·6	8·0	9·0	51·7
7 & 14 ...	6cwts. Superphosphate...... 2cwts. Sulphate Ammonia ..	13·0	17·5	17·9	12·0	15·9	76·3
8 & 16 ...	6cwts. Superphosphate...... 1cwt. Sulphate Ammonia ... 1cwt. Sulphate Potash	11·5	11·0	11·4	11·0	14·0	58·9
18 to 21	(? Commercial Potatoes)	14·8	14·0	12·9	14·0	14·7	70·4

Whilst it is not possible to arrive at any definite conclusion from such a limited series of experiments, several very interesting features appear to be indicated in the above Table.

In the first instance it will be noted that the lowest number of points have been gained by the potatoes that were planted without manure. This sample was awarded 43.3 per cent. and it would therefore appear that fertilisers play an important part, not only in promoting an increased yield, but also in the improvement of the cooking quality of the tubers produced.

Superphosphate has had influence in giving the cooked potatoes a clear creamy colour causing them to retain their shape, thus producing a more attractive appearance.

Sulphate of potash has apparently led to an improvement in flavour as in one instance the addition of this manure has increased the points for flavour by 3.6 and in the other by 3 in a maximum of 20 points for the division. It also appears to improve the texture but at the same time tends to give the potatoes a yellowish colour which is a disadvantage.

The potatoes with the best cooking qualities were obtained from the plot receiving 6cwts. of superphosphate and 2cwts. of sulphate of ammonia per acre. 76.3 marks were allotted to this sample, which was good in every section, but gained the highest points throughout the whole series for texture, flouriness and mash.

Next in the order of merit was the sample from the 3cwts. of superphosphate and 2cwts. of sulphate of ammonia plot, which was awarded 64.7 per cent. and also received high marks in the same three sections as the preceding sample.

Examining the cooking qualities of commercial potatoes it is interesting to note the regularity of the points allotted. In every instance, that is to say, in each section, they represent fair average quality and consequently provide a useful basis for comparison. From the results obtained it would appear likely that on the average potatoes harvested from the Murray Swamp lands will not equal those from other areas in colour, appearance, and flavour, but, on the other hand, will provide a foodstuff with better texture, flouriness and mash.

However, in a number of the tests they have proved quite satisfactory and there is every possibility that when efficiently grown and properly manured, tubers from these areas will tend to improve the general average quality of South Australian potatoes. As an example it may be pointed out that the crop receiving 6cwts. of superphosphate and 2cwts. of sulphate of ammonia gave a cooking test of 76.3 per cent., comparatively with 70.4 per cent. for commercial potatoes.

In connection with quality, emphasis must be placed on the necessity of thorough and careful cultural operations. Under the swamp conditions excessive moisture is a danger and a likely cause of damage, not only to the yield, but also to the quality of the tubers harvested. Regular and effective control of weeds, full hilling up of the plants and intercultivation between the rows, together with many other aspects associated with the growing of potatoes, need to be very carefully watched if success is to be attained and unless the intending grower is prepared to undertake these duties he should abandon the idea of planting this crop on the Murray swamp lands.

So far as manuring is concerned, it will be recalled that the greatest nett profit was gained when the crop was fertilised with 6cwts. of superphosphate and 2cwts. of sulphate of ammonia per acre, and in the last Table it has been shown that this same dressing has led to the production of tubers of the highest cooking quality. Moreover, these potoatoes were of good average quality in the matter of size and eyes, whilst they did not unduly deteriorate when stored.

It is therefore recommended that this dressing be adopted for potatoes planted on the reclaimed areas, but at the same time growers must keep prominently in mind the fact that careful irrigation and thorough cultural operations are of greater importance in the production of profitable good quality crops than any manurial dressing they may apply.

From the foregoing results it can be concluded that potatoes may be profitably grown on the swamp lands of the Lower Murray, but, as has already been pointed out, any expansion in the cultivation of this crop can only be possible if heavier yields and tubers of superior quality to those commonly available to-day are harvested. In this event growers in less favourably situated areas would not be in a position to compete and would ultimately have to cease operations.

However, unless disease, seepage or some other unforeseen factor interferes there is every reason to anticipate that sooner or later the Murray swamps will produce much of the State's requirements for potatoes.

Moreover, these areas would lend themselves to easy grading and inspection of the crop, thus resulting in the improvement of the quality marketed comparatively with that regularly offered at the present time.

The experiments conducted have involved a good deal of work and in conclusion, it is desired to place on record, our appreciation of what has been done by Mr. J. W. E. Schultz in the growing and harvesting of the crop, and by Miss Ellie Campbell in conducting the cooking tests.

AGE AT WHICH TO SELL PIGS.

Miram asks, "What is the most profitable age to sell pigs?"

Mr. H. B. Barlow (Chief Dairy Instructor), in reply, says that the most profitable age to sell pigs will depend wholly on local circumstances. Generally speaking, pigs are sold as weaners (8 weeks), porkers 3½-4 months), or baconers (4½-5½ months).

"I do not think any special age can be said to be the most profitable age, but the younger you can sell a pig and still obtain the top price, naturally the better the returns.

Pork pigs, weighing about 60-80lbs. dead weight, usually show about ¼d. to ½d.* per lb. better price than baconers weighing 120-130lbs., but the cost of freight, handling, and selling is usually the same in each case, and this may more than compensate for the price difference.

The large variations in price is not a question of age, but rather of type and condition of the pig.

Everything else being equal, the heaviest weight at which you can receive the maximum price per lb. will be found more profitable for the producer, but at the same time a bacon pig for the local market should not weigh more than 130lbs. dead weight, and should be procurable at not more than 5 to 5½ months of age if properly fed."

VALUE OF SUNFLOWER SEEDS.

The Mypolonga Branch of the Agricultural Bureau asked: "What is the feed value of sunflower seeds, and what is the best method of feeding same?" In reply, Mr. W. J. Spafford (Deputy Director of Agriculture) advises that although sunflower seeds contain a fairly high content of fibre (23 per cent.), they are a really good foodstuff for farm livestock, both animals and birds.

The starch equivalent figure for sunflower seeds, which is the guide to fattening properties, is 95.5, whereas wheat is about 77, barley about 78, and oats about 63. The nutrient ratio, which indicates milk-producing powers, is 1 to 5.2, against about 1 to 10 for wheat and barley, about 1 to 8 for oats, and about 1 to 3 for pease.

Sunflower kernels, which comprise about 55 per cent. of the seeds, have a starch equivalent of 122.5 and a nutrient ratio of 1 to 4.2. Sunflower seeds can be fed whole to all farm animals without injurious effects, and will be readily eaten by livestock if mixed with chaffed forage.

ACTIVITIES AT ROSEWORTHY AGRICULTURAL COLLEGE, 1933-34.

PART IV.—THE SILAGE HARVEST—METHOD AND ITEMS OF SPECIAL INTEREST.

[By ALLAN R. CALLAGHAN, D.Phil., B.Sc. (Oxon.), B.Sc.Agr. (Syd.), Principal, and O. BOWDEN, R.D.A., Farm Superintendent.]

With the risk of a certain amount of repetition, it is intended in this article to review the silage harvest of last year. In doing so, it will be necessary to incorporate some of the leading features of the previous season's operations, wherein experience was gained which led very largely to the successful and unusually large silage harvest of 1933. So that although this constitutes part of the report on activities for 1933-34, it actually summates the experience of the last two silage harvests; in fact, as far as silage stack building is concerned it is a record of experimental work, the results of which are considered to be of far-reaching importance in South Australia. Under the special circumstances and also in view of the increasing interest in this method of conserving fodder, a detailed account of the work is given.

THE NEED AND VALUE OF SILAGE.

At the outset a cursory interpretation of the actual need and value of silage is not out of place, for although the story has been written and told many times before, through constant repetition and insistence on the urgency of the need and the uniqueness of the value of silage, it is hoped that each year's figures will relate a substantial increase in the amount made in South Australia, until it is universally accepted as an indispensable means of fodder conservation. Actually the conditions which prevailed in our State during the first six months of this year must have emphasised more effectively than can be done by any other means the absolute necessity of fodder conservation on all farms where livestock are a feature. The desirability of livestock entering into the farming system has already been emphasised in the first of these reports, and there can be no doubt that the conservation of suitable fodder reserves is the fundamental factor at present involved to make such a practice wholly sound and reliable. It can only be partially successful, and fraught with the possibilities of occasional failure, where stock are maintained, yet called upon to subsist over lean periods on pastures, that, besides being scanty, have lost palatability, nutritive value, and all vestige of succulence.

The urgent need of the moment is to build up adequate reserves, firstly as an insurance against loss of stock, and, secondly as an insurance against serious decline in production. The first of these does not necessarily involve silage, for it is more a matter of maintenance, and for this purpose hay and grain can be, and should be, conserved to fill the requirements. The second factor concerns both maintenance and production; this can only be fully satisfied by the conservation of fodder which will combine nutritive value with succulence. If it were only a matter of maintenance or even fattening, then reserves of dry fodder and concentrates might well be advocated, but when milk production comes into the matter, and when the modern insistence on continuity of supply of primary products is given consideration, then dry feed in itself is not enough. This is especially true where cows and ewes suckling lambs are concerned, and silage as a succulent feed of known milking producing capacity is the only form of conserved fodder which really satisfies the needs.

During recent years there has been a marked increase in dairying; yet this year the dairy farmers are unquestionably in a serious plight and have lost as much as 40 per cent. of their normal returns because of the serious decline in actual production. The loss in the fat lamb industry has been equally serious because the owner has risked the chance of seasonal failure. To safeguard this increased production, to make sure of its continuity, and even to increase it, the preservation of green fodder in a succulent, nutritious condition becomes fundamental in a climate such as ours. The only answer at the moment is silage, for the evidence is conclusive that as a feed it answers the purpose of succulent feed for milk production, whether it be in the dairy cow or the ewe suckling lamb.

Very much more might be written on the need and value of silage, but nature itself has already this season brought examples of both the need for it and its value into sharp relief far more effectively than all the writing that might be done here. The work during the last two years at the College, in demonstrating by stack building the ease of its manufacture, as well as its value as a foodstuff, has already been widely appreciated, but appreciation is not enough, unless those appreciating are stimulated into activity in the matter.

THE PRESERVING PROCESS AND GENERAL PRINCIPLES.

Before entering into the details to follow, for the benefit of those not well versed in the process of silage making, a brief introduction to the salient principles involved, together with their practical implications, will be useful, and make later observations intelligible and more self-explanatory.

Illustration 1.—The knife bar of the mower with the curved iron rods attached. This was used in cutting self-sown clovers and cereal.

Silage is green fodder preserved in a succulent, nutritious condition by a process of *controlled fermentation.* If this fact is carefully borne in mind, many points which arise in practice would receive the commonsense interpretation they deserve, and much of the fuss and bother over what should and what should not be done would be eliminated, thereby removing confusing details and unwarranted technicalities from the mind of the farmer. The process is straight-forward, but it is one of *controlled* fermentation.

When any quantity of freshly cut green plant material is massed or heaped together, the first obvious change is a very rapid rise in temperature. The initial rise in temperature is due to the procedure of normal cell activity, but fermentation very soon follows. The accumulation of carbon di-oxide and the exclusion of air, which is essential to make good silage, destroys all life in the cells of the fodder, but under such conditions certain bacteria thrive. These

bacteria obtain the oxygen required for their existence from chemical compounds contained in the cell sap, and until a certain temperature is reached lactic acid bacteria are extremely active.

It should be remembered that the organisms which produce the preserving acids cease to do so at a high temperature, and the amount of acid produced will depend on the length of time at which the silage remains below a certain temperature (130-140 deg. Fahr.); this defines the quality of the ensilage and the efficiency of its preservation. The object should be to prevent excessive temperatures altogether, thereby prolonging lactic acid fermentation until finally checked, partly through the depletion of raw materials supplying the requirements for active fermentation, and partly as a result of the accumulation of substances which are toxic to bacterial life and which inhibit further activity.

Translating this very brief outline of the process into practice, it can be summarised in one sentence. The object should be to fill the silo, or build the stack, rapidly, using only freshly cut green fodder, and to bring the necessary pressure to bear to exclude air and cure the fodder with as little waste as possible and so preserve it in a succulent, green, and nutritious condition. *From this two main considerations present themselves, the first concerns the state of succulence*

Illustration 2—The rods attached to the mower worked effectively, the cut sward was rolled into a light wind-row, which greatly facilitated subsequent handling.

in the fodder, and the second the exclusion of air. If due emphasis is given in making silage to these two factors all the difficulties concerned will be overcome.

The fodder must be cut while it is still green and succulent and when maximum bulk can be expected. Whatever the plant, this stage is reached at flowering and continues after flowering up to the stage when the developing seed is still soft and milky. Later than this the plants begin to dry, they have insufficient succulence, and serious failures often result. So, as a general rule it is fundamental to begin silage cutting early, so that the final cuttings will be made while the fodder is still succulent. If the dough stage has been reached in cereals, for instance, the fodder is too dry and should be cut for hay rather than ensilage. In building stacks it is wise to use material of a more succulent nature than might be placed in a silo; it is important in fact not to attempt to make stack silage with comparatively dry material. If the fodder is too dry, fermentation is retarded, there is greater difficulty in excluding the air, overheating results, and the plant tissue becomes less nutritious, and may even become seriously charred

and a complete loss. For the best results, therefore, it is advisable to start early while the plants are fresh and green, even if the optimum stage has not been reached, rather than to commence when the optimum stage for cutting has been reached and finish up with dry over-matured fodder. There is a danger of this under South Australian conditions, where crops are apt to ripen off very suddenly during the spring and early summer. As a rule only as much crop as can be put into the stack or silo in the day should be cut, for fodder that has wilted makes inferior silage to that in a freshly cut condition.

The second great consideration is the exclusion of air, and this involves several of the most important practical points. It implies at the outset that everything possible should be done to make the fodder pack as closely, as tightly, and as evenly as possible; this in turn implies the application of weight or compacting pressure of some sort. Now in building stacks the easiest and most efficient means of applying pressure is to use the fodder itself, and from this one reaches the

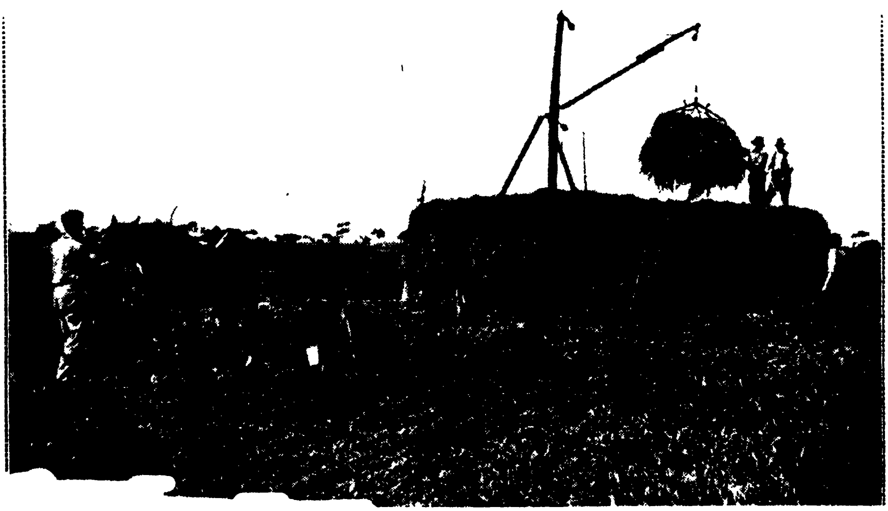

Illustration 3.—The grab-stacker is here shown lifting a load of fodder on to the stack.

golden rule of silage stack building, and that is don't sacrifice height for base room. By building on a small base and aiming at greater height the foundations of success are laid. In the case of a trench silo the pressure can be exerted easily by artificial means such as tramping with horses, or drawing a load on to the fodder, consequently depth in the trench has not the same significance as height in the stack.

The rapid building of the stack or filling of the silo is then desirable so as to bring pressure to bear upon the material as quickly as possible with the object of controlling temperature by excluding air and so extending the period of fermentation. This will result in the production of a desirable sour type of silage of good colour and odour. Dealing with sheaved cereal material, which being rather stemmy, is more difficult to pack than loose pasture especially clover or lucerne, weighting is necessary after each day's work to make the exclusion of air more rapid and certain. Then again if the fodder is on the dry side a liberal sprinkling with water, especially in stack building, will be found of great assistance.

THE SILAGE HARVEST OF 1933.

The total harvest of silage last year was easily a record for the College, and was made up from 490 tons of cereal, which was sown for the purpose, and 240 tons of self-sown material from Days A and B, a paddock that had been cropped to cereals the year before and which was being rested as ley land. This made a total harvest of 730 tons, and it was conserved as shown below:—

Silage Harvest, 1933.

Method of Conservation.	Material Used.	Source.	Weight Harvested.
Overhead Silos of reinforced concrete	Sheaved Oats and Barley, chaffed and blown into the Silos	Old fence plots and 5A. Now known as No. 5	300 tons
Stacks—			
(a) Two round stacks of loose fodder	Volunteer growth consisting mainly of Burr Medic (or Burr Clover) with admixture of self-sown wheat and oats	Days A and B	240 tons
(b) Pole-guided stack of sheaved cereal	Sheared oats and barley ..	No. 5	100 tons
(c) A round stack of sheaved cereal	Sheaved oats and barley ..	No. 5	90 tons

It is not for one moment suggested that such enormous quantities are required in the normal course of events, but when seasons of plenty do occur the very fullest advantage possible should be taken of them. Only by this means can a safe and sound policy of livestock management be carried out in an environment as notoriously unreliable as the one under which we, in South Australia, work. Poor seasons are inevitable, just as good seasons are; the only way to ensure an even tenor of production and to guard against failure is to utilise to the fullest extent the bounteous growth of favourable seasons. Every effort was made at the College last year to put this policy into practice, and as much fodder as could be handled was conserved. The sense of security and actual value of this was very soon exemplified, for the present season necessitated an unexpected early call on these reserves.

Under ordinary circumstances about 300 tons of silage are required at the College each year. This is because livestock feature so largely in conjunction with cropping, and ample provision must be made to tide over the regular summer shortage of paddock feed. Consequently it is customary to sow special areas of cereal for the purpose, or utilise certain areas of the season's crop. The decision to sow the 70 acres already referred to in the general harvest report was made because the reserves on the property at the close of 1932 were fairly low and offered no sense of security. The details of preparation, growth, and yields from this area have already been given.

Similarly, the source of supply of self-sown fodder from the fields Days A and B has already been detailed. It might be stated here, by way of emphasis, that such a luxuriance of feed might quite easily have been fed during the year, but in this way it could not have been utilised to anything like the full extent of its value. In fact the proper utilisation of it, without considerable wastage, would have been difficult, but converted into silage and hay, as it was, not only meant that fuller feeding value was obtained, but even as an insurance policy its worth was greatly enhanced.

The gathering of the fodder was quite a big undertaking, but the nature of the season was such that an early start was made and all operations connected with silage were completed before hay cutting was commenced. The volunteer growth in

Days A and B was taken off and stacked first; these operations beginning during the first few days of September. The overhead silos were then filled, followed by the pole-guided stack, and finally a round stack of sheaved fodder.

CUTTING AND HANDLING THE FODDER.

Sheaved Fodder.—The actual cutting, and handling of the fodder from the field to the silo, are matters of particular practical importance, as certain difficulties present themselves. The fact that the fodder has to be handled while still green and succulent complicates the whole position. It is of greater bulk, and considerably heavier than if handled as hay, and it is often cut before the ground has

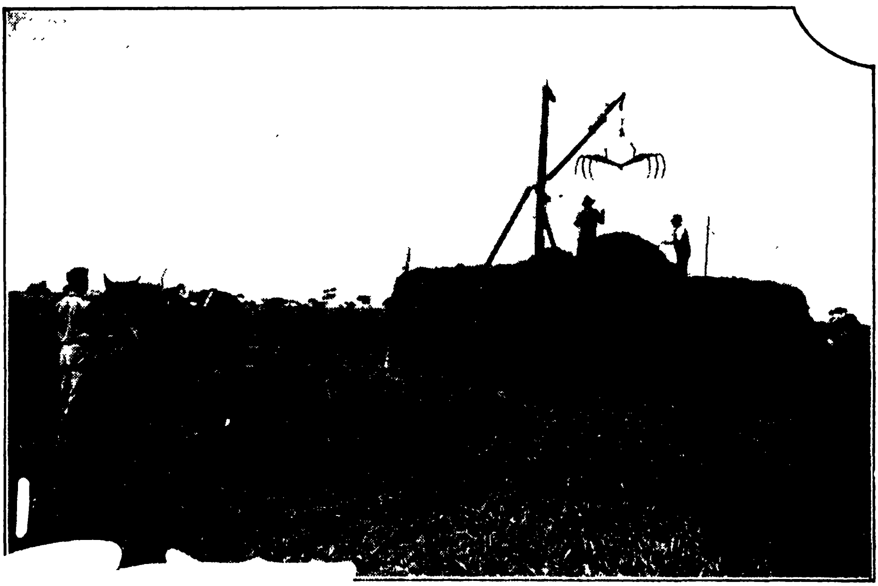

Illustration 4.—The same load just dropped; the grab is open ready to be swung out and lowered for the next haul.

dried out properly after the winter rains and while undergrowth is still at maximum bulk and still very sappy. For the last two seasons now, some trouble has been experienced in binding the cereal crop meant for ensilage. These difficulties, however, are not insuperable and normally only present themselves during the first week of operations when both ground and fodder are damper than later on, but a note here may save endless trouble for someone. With the damp conditions and the heaviness of the normal sheaves, the load on the machine is heavy, causing the big wheel to slip, whereupon the machanism ceases to operate and the fodder jams. Experience at the College is that this can be overcome sufficiently well, provided the binder is in good general condition, by keeping the knife sharp and making provision to bind smaller sheaves. It is considered that by fitting an auxiliary engine to the binder to relieve the load it would be quite possible to work under all conditions likely to occur.

Once bound, the subsequent handling of the material was comparatively simple, though such work is considerably heavier than handling sheaved hay or sheaves meant for threshing. Normal procedure was to cart directly following the binder, no preliminary stooking of any kind being necessary, as the fodder was ensiled the same day as it was cut.

Loose Fodder.—Where the binder is impracticable, such as in clover or lucerne, the only available machine is the mower. The area of self-sown material harvested at the College last year was chiefly Burr Medic, or Burr Clover as it is commonly called. This formed a dense growth about a foot high and was fairly typical of the growth common on areas of subterranean clover.

The ordinary mower leaves the green fodder in a rather unsatisfactory way for further handling, and to alleviate this a series of curved rods was attached to the mower knife bar. These rods were placed 9in. apart. Each succeeding rod was longer than its neighbour, with the longest immediately behind the machine as the first illustration shows. This device delivered the cut sward in a roll approximately a foot thick, which is well depicted in the second illustration. The action of the rods was very interesting, and they operated with greater efficiency than at first anticipated.

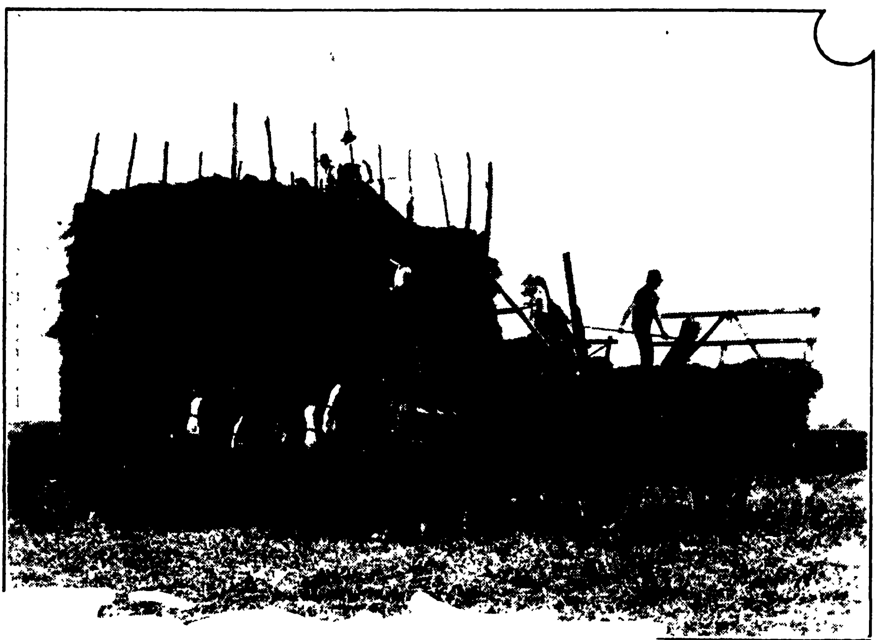

Illustration 5.—The first pole-guided stack built at the College. Note the sheaf heads hanging over the end of the stack in alternate layers. Lower down these have been chopped off and thrown into the centre of the stack.

The rods were all attached to the knife bar by boring holes in the back of the bar, the shortest of which was attached so that it just missed the end of the outer dividing board and was then hooked upwards. The result was that the partial turn, obtained when the sward was pushed across by the outer board, was completed by this rod; succeeding rods then continued the turn until the sward was rolled clear of the last and longest rod behind the machine. This had distinct advantages; the horses did not trample on the material in the following round and the sward was also more accessible for picking up and for loading on the sweep rakes. The sweep rakes used for the work were made at the College and saved a tremendous amount of heavy lifting. Unfortunately the ground was rather too wet and generally uneven to enable the sweeps to sweep in the fodder as originally intended. A little was gathered in this way, but for the most part

the sweeps were loaded, then hauled to the site of the stack and tipped. A grab stacker, working at from two to three minute intervals and taking 4cwts. to 5cwts. at each lift, dealt quite effectively with the loads being delivered by the sweep rakes. Illustrations 3 and 4 are photographs of the grab and tackle at work.

In describing the ensiling of the fodder it will be expedient to deal with the methods separately, but as the filling of the overhead silos was done in the ordinary routine manner, no special mention need be given here, especially as there is nothing new to cite. Obviously initial expense rules the overhead silo out of consideration, except where reserves are stored for dairy cattle or stud stock, and where it is regularly used and refilled every season.

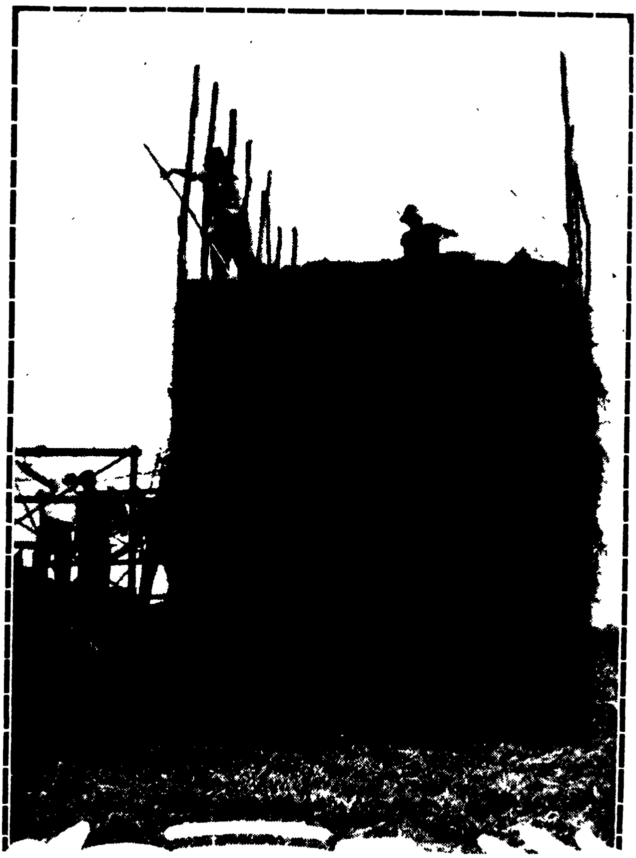

Illustration 6.—An end view of the pole-guided stack. The builder, it will be noted, is placing all the sheaves in parallel fashion, the heads facing the camera. In the previous layer built the butts face the camera, and so on.

Out of justice to the trench silo system, however, it should be mentioned that where a suitable site and conditions are available the trench offers many advantages. At the College, however, two factors make the trench silo less attractive; firstly the flatness of the country with no guarantee of good drainage, and secondly, the limestone soil, with rubble-like subsoil on all sites which are satisfactorily drained, would necessitate lining of the trench to make the walls permanent and suitable. For this reason some cheap and effective means were

C

sought. The following descriptions of the stacks built at the College during the last two years record the experience gained, and indicate that stack ensilage of good quality and low manufacturing ... use and at low cost.

TH...

This method was first tried at the College in 1932; it proved an unqualified success and last year it was successfully repeated. The method has so much in its favour that its further use is being more fully and permanently exploited to the extent of putting up permanent frameworks which may be regarded as stack

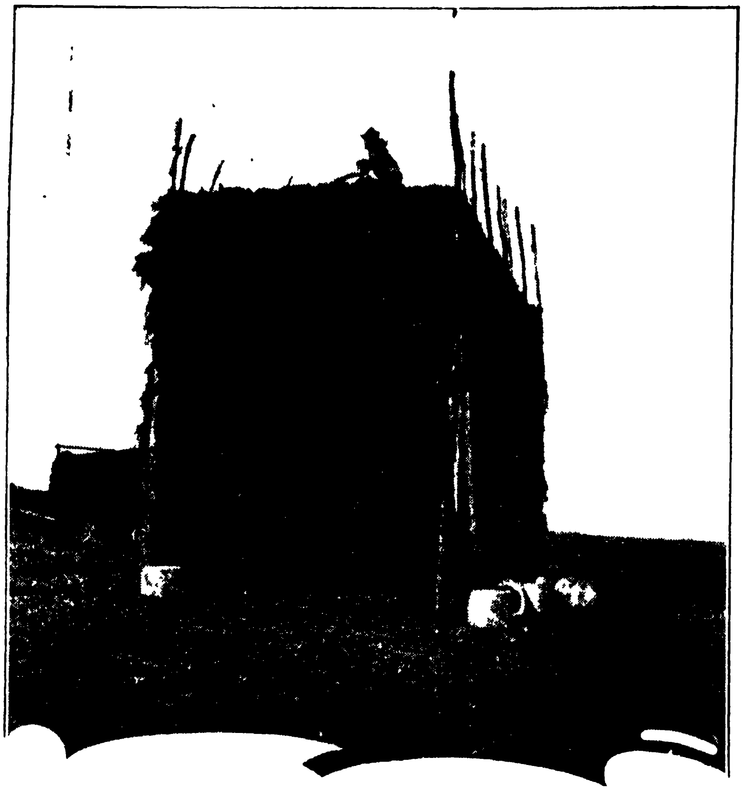

Illustration 7.—A general view of the pole-guided stack nearing the top of the poles for the first time. Note particularly the tarpaulin used to protect the windward side, and the old concrete horse-troughs on the ground, which were suspended by wires thrown over the stack and thus used as weights after each day's work.

silos. The system is to build a framework of poles of reasonable strength and rigidity along both sides of the stack. The poles used at the College were cut from a plantation of gum trees on the property. The rectangular frame used was designed to hold from 90 to 100 tons, and the dimensions were 21ft. by 12ft. and the poles were 22ft. out of the ground. Along the two sides, the long poles (of from 6in. to 8in. in diameter) were placed firmly in the ground 3ft. apart; eight poles were thus required for each side. Opposite poles were braced by wires across the top of the stack.

For a farmer in a position to get long poles conveniently, a stack frame of the dimensions 21ft. by 14ft. 6in. would probably be more manageable; the increased base-room being necessary to reduce the height slightly. If a stack

built in a framework of the dimensions suggested is raised to a height of 20ft. and filled to that height, say, three times after allowing for settling, 100 tons of ' ...ed cereal greenstuff would be required.

This type of stack for sheaved cereal fodder respects the principles of ensilage manufacture in a way that no other stack of similar material does. It offers several distinct practical advantages as well, but its greatest advantage lies in the fact that it enables the stack to be built with sheaves set in parallel fashion, and not with the butts to the outside of the stack, except at each end, and then

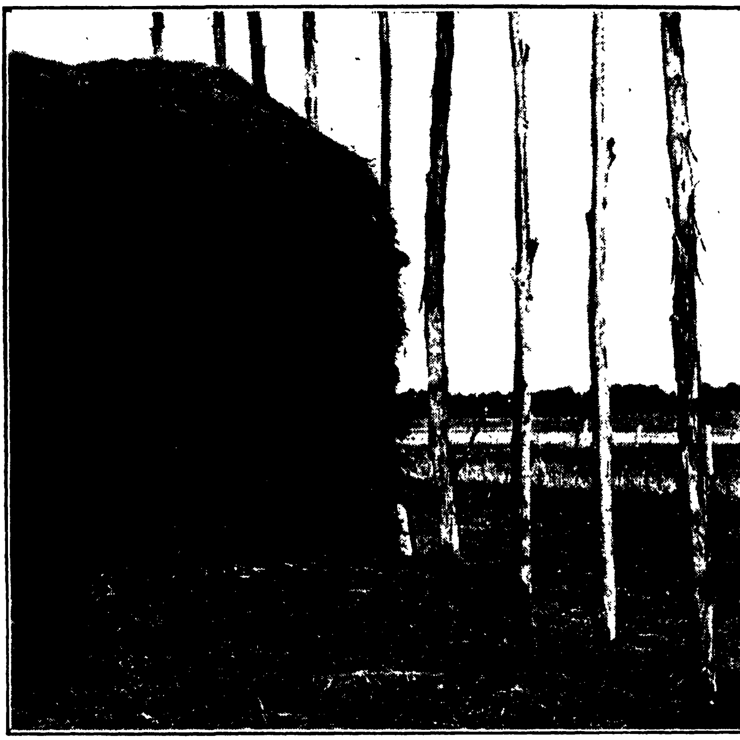

Illustration 8.—This shows the pole-guided stack as it opened. Note how compact and solid the silage is, and how little the margin of wastage extends into the bench.

only in alternate layers. When building the stack it was found very advisable to lay one layer of sheaves with the heads all facing one direction and all parallel to the sides of the stack, the next layer with the heads facing the opposite direction, and so on, so that at each end the heads were allowed to protrude over the end edges of the stack in alternate layers. These were then trimmed level with the butts of the alternating layers and thrown back into the middle of the stack. This feature of the stacking method is illustrated in the photographs.

Actually the parallel stacking of the sheaves is made possible by the poles, and this is undoubtedly the most important attribute of the method, for such parallel stacking of the sheaves enables much better compaction and it guarantees the exclusion of air quicker and far more effectively than if the stack were built on the haystack principle, where sheaves are criss-crossed to bind them together. Further, the poles facilitate building and make the chances of serious slipping

of the stack during bu... [illegible] ...n this respect the chances of slipping will [illegible] ...me, but provided reasonable care in building is taken, very little trouble need be feared.

In building the pole-guided stack about 20 tons of green fodder were being dealt with each day. This in itself [illegible] ...ght and pressure on under layers; even so, with this type of stack, it was considered necessary to apply additional weight overnight following each day's work. To do this four planks were thrown on top of the stack, two being set along the two long edges. Wires were then thrown over the stack and rested on these planks and weights were suspended on the ends of the wires. For the purpose old concrete horse troughs were used, but any heavy logs would fill the bill quite well. The method adopted was to roll the weights on to empty trollies on either side of the stack, attach the wires, then on removing the trollies the weights were suspended to bring pressure upon the stack. The experience gained indicates that if proper attention is given to weighting during building much of the need for heavy final weighting is overcome. Actually in the case of the first stack built at College on this principle the same weighting was used after the stack was finished as had been used during the building with quite satisfactory results. Certainly if the stack is intended to stand as a reserve for longer than six or eight months, more substantial weighting is advisable.

Stacks of sheaved cereal fodder can be made without the poles. These have to be built in much the same way as a haystack, and the experience gained at College over the past two years has been sufficient to indicate that such stacks of silage are easily the most difficult to build. A rectangular or nearly square stack was tried in 1932 and a round one last year, and although the round stack gave less trouble through uneven settling and tendency to slip than did the square type, both showed wide bands of wastage and the manufacturing loss was high. In contrast to both, in the two years the pole-guided stack stood out in very sharp relief, the marginal loss was very slight (Illustration 9), and the manufacturing loss surprisingly low. In respect to the latter the loss due to manufacture in the 1932 stack was actually ascertained by chemical analysis and found to be no greater than in the silage made in the overhead silos (in fact the figures indicated a slightly better result in the stack). Apart from the difficulty of maintaining even settlement in stacks built on the haystack principle, it is practically impossible to drive the air out on account of the locking and crossing of sheaved bundles. This is the real cause of marginal and manufacturing loss, and the most successful way to overcome the trouble is to build on the parallel system as suggested in the pole-guided stack just described.

THE LOOSE STACK.

The gathering of the fodder by means of the mower with rod attachments, sweep rakes, and grab stacker has already been described. For handling pasture, clovers, or lucerne as loose material, the method is unhesitatingly recommended, and it will be found to be quick, economical, and easy.

For the work under review a convenient and yet reasonably well drained site was chosen for stacking, and here the grab stacker was erected and a base of 24ft. in diameter prepared. In choosing the site convenience of handling the fodder was considered, and this is an important point, for quick building is often the essence of the contract. Besides facilitating the handling, it is cheaper and more economical of labour than carting the fodder out of the paddock to meet any feeding conveniences which might suggest themselves.

The trouble of keeping sheaved stacks from uneven settling is not so pronounced in stacks built of loose clover material, and in the stacks built at College there was, if anything, a draw to the centre, where more rapid settling appeared

to t..... place. This rather quick settling in the middle had a tendency to pull the ...es inwards and some heaping in the centre was found advantageous during the later stages of building. Apart from this, the usual practice in silage making of keeping the surface practically level during the building was followed, hearting up taking place as the stack neared completion, and as a final mounding up.

In all silage stack building at the College the side exposed to the prevailing wind is protected by a tarpaulin; this saves endless trouble due to the temperatures of one side of the stack being greater than those on the other, which induces, quicker than anything else, uneven settling, which is invariably accompanied by a tendency to slip. No trouble was experienced with the two loose stacks built and they were both brought to the maximum height of the grab (about 18ft. to 19ft.) on three occasions before they were closed and weighted down.

The first stack built was made of particularly succulent fodder and seepage and general weeping of moisture set in before the stack was finished. This increased and continued for some time after the stack was weighted down. With this oozing of juices from the stack a very objectionable odour developed as soon as it made contact with the air. This odour persisted for about two months and is to be expected from leguminous fodder made into ensilage when portion is exposed to the air, as is the case in a stack. Normally fodder rich in proteins makes a product of higher odour than that rich in carbohydrates, but well made it is never objectionable, except in the manufacturing process when seepage or outside portions of the fodder are exposed.

The second stack was slightly smaller than the first and it was built slower, because labour was not available regularly during the Royal Show week. The fodder was also drier, and the lack of labour to assure quick handling meant at times rather serious drying out of the material, but this was rectified by the liberal use of water which was sprinkled over the fodder during the course of building. When delays did occur this stack was weighted down pending a continuance of operations, and before it was finally closed 11 days had elapsed from the time of commencement. There was also seepage from this stack and a high odour accompanied the manufacturing process.

The above facts are stated in connection with this second stack as it has since been opened, and although some defects in the fodder might have been explainable, none required any explanation. It proved to be first class, and dry stock even consumed the darker outer margins which might legitimately have been considered wastage. Experience from this result make it possible to state here, that, provided adequate care is taken to weight down during the intervals, the stack can be left for a day or two, and that at least 12 days can be taken with safety in handling 120 tons of similar fodder in this manner. Further, objectionable odours and heavy seepage from the stacks do not infer bad silage; rather, the reverse, for the bad odours are accompanied by seepage which helps to seal the stack and seepage indicates, amongst other things, that the air has been effectively driven out of the fodder.

GENERAL HINTS ON STACK BUILDING.

Having outlined the method adopted at the College in silage stack building a few general hints applicable to ensilage ensiled in stacks may be useful.

Under no circumstances can the sides of an ensilage stack be built out as is allowable and attractive in haystacks. The stack should be narrowed in gradually as it is being built, that is, with the sides just off the perpendicular, sloping inwards. In the pole-guided stock, of course, they should be perpendicular, but here the poles prevent slipping. Great pressure is exerted on the fodder below, and unless the sides are perpendicular or broadening at the base trouble will accrue as the settling takes place.

When building great attention should be paid to the walls and corners of the stack to see that they are well compacted. The centre of the stack should be kept full, but not hearted up as in the haystack, the idea being to keep the surface as near level as possible and the walls and corners as firm and tight as possible.

Uneven drying and uneven temperatures in the stack may be brought about by wind on the one side drying it and driving the temperature to the other side. This causes uneven settling, and uneven settling above everything else must be guarded against or the stack may slip so seriously as to topple over. If a large tarpaulin is used to protect the sides of the stack from the prevailing wind, this will be found not only efficient, but actually indispensable in some cases. Great care should be taken to build evenly, even layers of fodder should be evenly distributed.

Illustration 9.—A close-up of the base of the open pole-guided stack, showing the very small margin of wastage and the dense compaction of the silage in the main part of the stack.

The matter of weighting down after the day's work will depend upon the amount of fodder built on each day. At least 6ft. of fodder should be added daily for good results. This in itself is another good reason for keeping the base small. In a loose stack of clover or lucerne, or fairly fine pasture, weighting down every day may be dispensed with, but with stacks of sheaved fodder it is essential. For the purpose, the use of weights suspended from wires thrown over the stack at intervals of at least every 4ft. will be found convenient. Special attention should be directed to see that a wire is run close to the edges of the stack. Under the wires on top of the stack throw a few poles or planks; this distributes the weight evenly, which is important.

Top the stack off, allow for settling, retop, and repeat, say, three or four times.

The whole should then be weighted down permanently. The recognised formula for weighting down is 1cwt. per square foot of surface. The weights used and the manner of weighting will depend upon the type of stack and whether it is intended to open the stack early or leave it for a longer period. At College, stacks are not expected to stand for very long, consequently the weighting is more temporary than would be the case if the fodder were to be held in reserve for a longer period. For the purpose at College heavy wood is piled on top. The advantage of this is ease of handling, stone, sandbags, earth, or other heavy material may be used, and for a more permanent weighting a framework of sandbags or stones round the outside to hold extra weight and make sure of distributing it right to the margins of the stack is desirable.

APPROXIMATE COSTS.

To many farmers the subject of ensilage brings to mind a gloomy picture of hard labour and imaginary high costs. Yet this year one might venture to assert that many are already conscience stricken and financially poorer for not having taken the matter seriously and placed some fodder in reserve when it was plentiful. The man who makes silage instead of hay is never tempted to sell his reserves when prices do rise, and when others are paying high prices for feed,

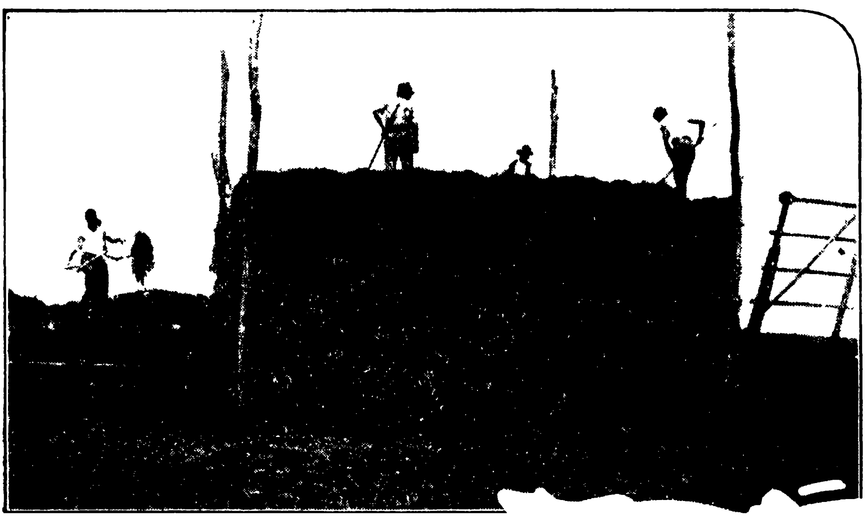

Illustration 10.—Stacks built of sheaved cereal on the haystack principle were not nearly as successful as the pole guided stack. The fodder was much darker, less succulent, and less nutritious.

he is in the happy position of being able to look back on the effort of the silage harvest with satisfaction. Whereas he employed labour to gather fodder which was available in plenty, it cost him only a fraction of what it would cost him had he to turn to, when prospects were bad, and buy fodder at shortage prices and at a time when he felt his money was most valuable. Surely the security, the insurance against a certainty and the obvious financial saving is a business proposition which every man on the land caring for his livestock must appreciate.

In order to give producers some idea of the costs, the estimated costs of the silage made at College last year are given as near as they can be assessed with any degree of accuracy under the special conditions prevailing. Actually the figures quoted below represent a cost which, if anything, errs on the side of being too high.

For labour at College students are practically relied upon, and the difficulty of estimating labour costs under the circumstances is obvious. Apart altogether from the difference in keenness and ability and devotion to the work in hand from the point of view of individual usefulness, an embarrassing number might be available some days followed by too few on other days. Taking a general view it is considered that for the purpose of valuing such labour it can be set down per individual as approximately half that of an experienced man, who would normally receive the basic wage for an eight hours day. On this basis, therefore, student labour has been charged at 5s. 3d. per day of eight hours, and this is considered to be a very high valuation, based as it is upon basic wage rates.

To arrive at the costs, the actual time, labour, and tonnage handled is reduced to unit equivalents per day. In this way direct comparisons can be made. The building of the loose stacks of volunteer growth, amounting to 240 tons, required 202 student-days and 46 men-days, which makes in all a labour cost of 6s. 5d. per ton. The ensiling of 300 tons in the overhead silos required 102 student-

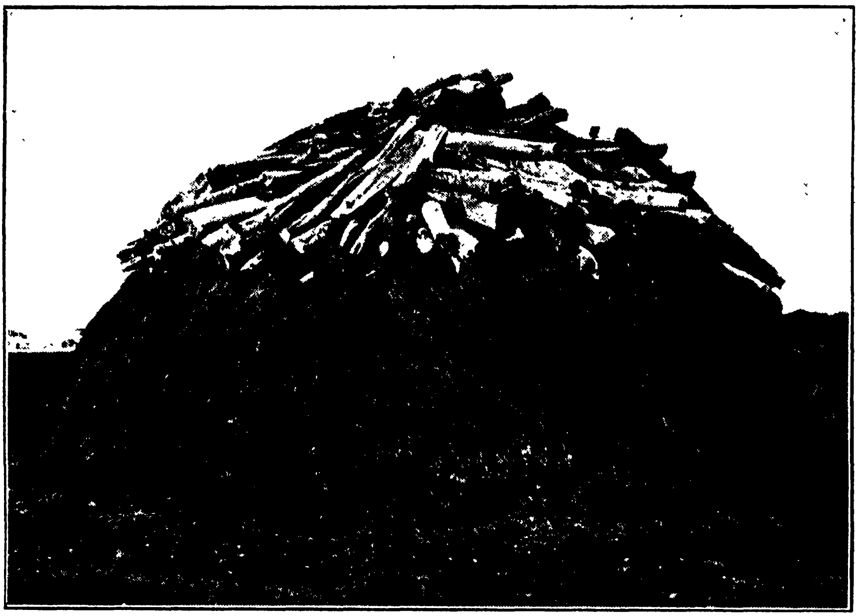

Illustration 11.—One of the Loose Stacks made from volunteer growth consisting chiefly of Burr Medic (or Burr Clover) and self-sown cereal. One hundred and thirty tons of fodder were ensiled in this stack.

days and 35 men-days, making a labour cost here of only 3s. per ton. This figure is low chiefly because of high yields obtained, and it is hardly fair to compare this cost with that of the loose stacks above, but in the building of sheaved stacks taken from the same cereal crops the costs are comparable. Here 58 student-days and 14½ men-days were required to handle and stack 190 tons, making a tonnage cost for labour of 2s. 5d.

Having assessed labour costs, the other items of expenditure remain for consideration. In this regard there is depreciation of plant and horse cost, which should be debited against such work. On the other hand rental or interest on capital is a matter which would accrue whether silage were made or not, and consequently for the purposes of these comparisons it is omitted.

As an offset to the low handling costs of cereal fodder ensiled in the overhead silos and in the sheaved stacks it must be remembered that crops were grown for the purpose and the costs of this production must be assessed. Whereas in the case of the loose fodder collected from self-sown areas no production costs need be considered, the only possible charge that could be made against such areas is loss of grazing during the period when the paddock was closed to livestock.

On the basis of the above the following table presents the approximate costs of the three types of silage made at the College last year.

Approximate Silage Cost at Roseworthy College, 1933, *based on Cost per ton and Labour at Basic Wage Rates.*

Type of Silage.	Production Cost.	Labour Cost.	Plant and Horse Cost.	Total Cost per Ton.
	s. d.	s. d.	s. d.	s. d.
Loose stacks	—	6 5	1 2	7 7
Overhead silos	2 8	3 0	2 6½	8 1½
Sheaved stacks	2 8	2 5	1 5	6 6

In the table, production costs include preparation of the soil, cost of seed, superphosphate, and seeding, together with expenses involved in harvesting.

The costs under the heading "plant and horse cost" include interest, depreciation, and renewals on implements for the time they were used. These costs also include an annual cost of the silo in the case of the overhead silos (which was estimated at 1s. 4d. per ton) and the annual cost of the framework for a pole-guided stack (estimated at 3d. per ton).

From the foregoing it is apparent that in years of plenty, when bounteous growth occurs, silage can be made without excessive and elaborate equipment, bother, or expense.

THE IMPORTANT PASTURE PLANTS OF SOUTH AUSTRALIA CONSIDERED AS TO THEIR IDENTIFICATION AND CHARACTERISTICS.

[By E. M. HUTTON, B.Ag.Sc., Field Officer.]

(Continued from page 60.)

4. RED CLOVER *(Trifolium pratense)*.

This is a highly palatable, hairy clover with upright stems. It develops a strong taproot which exploits the subsoil. Like other true clovers, the three small leaflet stalks are equal in size. Each of the large oval leaflets possesses a cream arch. (See Fig. 30.) The large stipules, which are longer than broad, are membranous with greenish-purple veins, and end in long hairy points. (See Fig. 31.) The small reddish-purple flowers are clustered into large dense heads. After flowering the petals become brown in colour. As it is essentially a spring and summer grower, it can be grown successfully in South Australia only under irrigation, or in our high rainfall districts, *e.g.*, lower South-East and parts of the Adelaide Hills, where the spring and summer are mild. In addition, this clover will only thrive on well-drained loams.

A. B.

Fig. 30—A: Giant colonial cow grass *(Trifolium pratense perenne)*. **B: Red or broad clover** *(Trifolium pratense)*.

[*From "G. and N. Catalogue,"* 1934.

In general, it can be regarded as a biennial only. Allowing the Red Clover stand to become mature and form seed has the effect of greatly reducing its life. The life of a Red Clover stands depends largely on the strain. The ordinary broad Red Clover is the shortest lived strain. Montgomery Red Clover, a more prostrate strain with a longer life than ordinary Red Clover, appears to have a definite place in pasture mixtures for the irrigated Murray Swamps. Giant Colonial Cow Grass or Perennial Red Clover (*Trifolium pratense perenne*), which possesses lance-shaped leaflets, is the most vigorous strain, and is also longer lived than

ordinary Red Clover. Giant Colonial Cow Grass and Ordinary Red Clover are best suited to cutting for green feed, ensilage, or hay because of their upright habit of growth.

In New Zealand, the bumble bee (*Bombus sp.*) plays an important part in the pollination of Red Clover.

5. ALSIKE CLOVER *(Trifolium hybridum).*

This clover is supposed to have originated from a cross between Red and White Clovers. It resembles Red Clover in appearance, but is practically hairless, has no cream arch on the leaf, and possesses stipules drawn out into a very long tapering point. (See Fig. 31.) The pale pink flowers are clustered into a round head. (See Fig. 32.)

It flourishes on heavy wet soils, and is also successful on acid soils, and those liable to waterlogging (cf. Strawberry Clover). It makes most of its growth during the winter and spring, and withstands frosts particularly well. Like Red Clover, it will not persist under hot, dry summer conditions. In South Australia

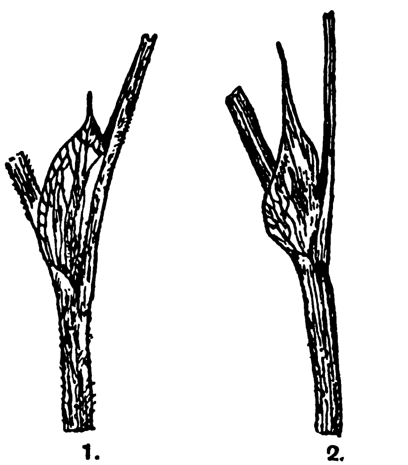

Fig. 31—Showing stipules of: 1, Red Clover (*Trifolium pratense*); 2, Alsike clover (*Trifolium hybridum*).

[*From "Agricultural Botany," by John Percival.*

Fig. 32—Alsike clover (*Trifolium hybridum*).

[*From "G. and N. Catalogue,"* 1934.

this clover could be of use probably on heavy ill-drained soils, which are not suitable for White and Red Clover. It appears to be very low in yield on the irrigated Murray Swamps.

6. BERSEEM CLOVER *(Trifolium alexandrinum).*

This is a vigorous annual clover possessing succulent stems and leaves, and having an upright habit of growth. The leaflets are characteristically lanceolate, and the yellowish flowers are clustered into a long head. It is an autumn, winter, and early spring grower. As it produces heavy crops of succulent herbage, and needs to be established before the cold of the winter, it can only be handled successfully under irrigation.

7. CLUSTERED CLOVER (*Trifolium glomeratum*).

This is a prostrate, hairless, annual clover, which can be confused with White Clover, because of the faint white arch in the centre of the leaflets. As pointed out before, the stipules end in sharp green points, and the leaflet margins are distinctly toothed. In White Clover the stipules are very different from those of Clustered Clover. The pink flowers are arranged in small, characteristic globular heads. It has often been called "Ball Clover" because of the shape of the seed head.

This highly palatable clover is found extensively throughout the settled areas. It is often badly attacked by lucerne flea. In late winter and spring, it produces a fair amount of useful feed. As far as South Australia is concerned, Clustered Clover appears to be a useful legume in the 16in.-20in rainfall country.

Fig. 33—Hop Clover (*Trifolium procumbens*).
[*From "Black's Flora of S.A."*

Fig. 34—Narrow-leaved Clover (*Trifolium angustifolium*).
[*From "Black's Flora of S.A."*

8. WOOLLY CLOVER (*Trifolium tomentosum*).

This annual clover is very similar in appearance to Clustered Clover, except that the flower heads become enlarged and woolly at maturity. It is very palatable, but not nearly as vigorous or abundant as Clustered Clover.

9. HOP CLOVER (*Trifolium procumbens*).

This hairless annual clover produces little leaf, is stemmy, and very low in productivity. The leaflets are pale green, and the slender upright stems become dark in colour. This is an example of a true clover, which has the central leaflet stalk longer than the other two. Thus at first sight it may be mistaken for a Medic. The stipules are turned back like the points of a stiff collar. The yellow papery flowers are clustered in a dense head. (See Fig. 33.) Although widely spread, this clover is of little use.

10. HARE'S-FOOT CLOVER (*Trifolium arvense*) and NARROW-LEAVED CLOVER (*Trifolium augustifolium*).

These hairy annual clovers are common in the settled districts. Stock will not eat them because of their unpalatability. Narrow-leaved clover has long pointed leaflets, and the long flower head has a tendency to become prickly at maturity.

(See Fig. 34.) Hare's foot Clover has long narrow leaflets with a notch at the tip. In addition, the base of the leaflet stalks are reddish-purple, and the flowers are clustered into small globular furry heads.

11. KNOTTED CLOVER (*Trifolium striatum*).

This is a hairy, prostrate, annual clover with diamond-shaped leaflets, the leaflets ending in a point. The leaflets possess a few dark fleckings. The stipules are hairy, and the long, green, hairy stipule tips have a tendency to turn back. It possesses small pink flowers, the seeds being formed in almost globular heads.

Knotted Clover occurs in the Adelaide Hills, and is eaten readily by stock.

(To be continued.)

THE BAKING QUALITIES OF AUSTRALIAN WHEATS.

No. 4.—The Quality of (a) Commercial Samples of South Australian Wheat and (b) Some Pure Lines of Ford.

[By A. R. Hickinbotham, B.Sc., Dip. Ed., A.A.C.I., Chemist, Agricultural College, Roseworthy.]

(a) Commercial Samples.

The Wholemeal Fermentation or Pelshenke Test (this *Journal*, June, 1934) is widely accepted as a reasonably reliable test for "quality" in wheat, and it has been used in an attempt to examine the importance of the various factors that might influence the quality of the grain grown in this State. In a general way, the quality of a sample is considered to be determined chiefly by hereditary factors, and by the climatic, and to a less extent the soil, conditions under which it is grown. From the data presented below, it appears that the hereditary factor is the only one of major importance in the wheatgrowing areas of South Australia.

Through the courtesy of the Director of Agriculture, over 300 samples of wheat of various varieties were obtained from the 1933-34 harvest, and these included grain from practically every important wheatgrowing district. Unfortunately for the purposes of comparison, nearly 40 varieties were represented, and of some of them only one or two specimens were received. Eight varieties accounted for 245 samples, and each of these varieties was represented by six or more samples (Table I.). Only four varieties were received from all of the seven Agricultural Districts and these four have been considered in compiling most of the following Tables, because an estimate of the potential quality of the wheat grown in different districts can be obtained from these data only if the districts are made to compete on the same basis, *i.e.*, with the same varieties; to include a high quality wheat grown in only one or two districts would invalidate the comparisons.

Table I., which gives the Test Number distribution for eight varieties, shows clearly the inferior quality of Gallipoli, which accounts for 30 of the 31 samples that gave a test of less than 30; the odd sample was labelled Ford, but is thought to be Gallipoli too. Gluyas and King's White are also of poor quality, while Nabawa, Ranee, and Sword are rather better. Ford is distinctly better than any of these, the results suggesting that it is a really good medium quality wheat. Florence, though extremely variable, is the best of the group. The highest testing lines of each variety have been planted, and their field performances will be compared amongst themselves, and with those of corresponding commercial seed. They will also be studied to determine whether they have inherited similar quality to that of their parents.

Most of the varieties exhibit a rather wide range in quality, for a sample giving a Test Number of 30 minutes is definitely weak, while one which gives a Test Number of 100 is of better than medium strength. A comparison of both the distributions and averages for districts, with those for the State (Tables I. and V.), suggests that the reason for this is probably not entirely a matter of differences in climate, but that differences in strain within the varieties are playing a part, and that some, at least, of these varieties may not be fixed for quality. Table II. shows the Test Number distributions of single plants of a few varieties, and also for a number of lines of Ford, each of which is the progeny of a single plant. These data, when considered alone or in comparison with that of Table I., support the contention that stronger lines may be obtainable by selection from some established commercial varieties.

Grain that is pinched has always been found to give a higher test than corresponding normal samples, the increase usually amounting to between 10 and 20 per cent. The extent to which this effect operates in these samples is illustrated in Table IX.

It is generally believed that an increase in available nitrogen in the soil improves quality within limits, but that the phosphate supply has little effect. The data given in Table VI. indicate that, if superphosphate does have any effect, it is slight. There is a noticeable tendency, particularly in the case of Nabawa, for quality to fall with increasing dressings, but the effects of low phosphate supply, low rainfall, and pinched grain on quality cannot be separated. For example, 36 of the 57 samples of Nabawa came from the four districts showing 30 per cent. or more of pinched grain (Table X.), and these are also the districts where, on the average, lower dressings of phosphate were used. Thus, it appears that pinched grain is tending to raise the apparent quality rather than that phosphate is lowering it. Table XI., which divides the samples according to both plumpness and amount of superphosphate used, indicates that plumper samples do tend to be associated with adequate supplies of phosphate, though, again, the effect is not marked. Possibly the very hard finishing conditions experienced throughout the State upset normal relationships in this respect.

It is sometimes asserted that high quality is associated with low rainfall, though it is more generally thought that finishing conditions are of greater importance. Hard finishing conditions were experienced throughout the State last year, so that the effect of this factor cannot be examined. Table VIII. shows the effect of differences in rainfall on the quality of these samples and suggests that, for the variations experienced in this State, quality is not appreciably affected by rainfall. Really wet conditions are not represented in the data; the bulk of the

"high" rainfall group were grown with less than 25in., and the highest fall recorded for any sample was 28.75in. In the case of Nabawa, a fall in quality appears to result under wetter conditions, but this is possibly due to other causes as in the similar case for phosphate with this variety.

The influence of the class of soil on quality is a matter upon which opinions vary. In Table VII. the soils upon which these samples were grown are classified into four broad types, those in which a limy subsoil or surface occurred being classed together as calcareous. In these samples the class of soil has had no effect on their quality.

In comparing the quality of the samples from each district (Table V.), no important differences are apparent, though there is a slight tendency for wheat from Upper Eyre's Peninsula to be a little better than average, while that from the Lower North falls slightly below the average. The Central district is helped by a high proportion of pinched grain, and the South-East is handicapped by a high percentage of plump samples. For this particular comparison, however, the districts are too wide, but the data are insufficient to permit of grouping into smaller units. There is, at least, a suggestion of an appreciable measure of uniformity in the quality of grain grown throughout the State.

In all these comparisons the possibility of certain strains of the varieties predominating in each district is an upsetting factor and, in an attempt to eliminate it, an effort is being made this year to secure similar samples grown from one strain of one variety by distributing the seed from the College, and to secure the general data in such a way as to permit of grouping it to represent districts on a natural and economic, rather than on an arbitrarily defined basis.

Finally, these samples were used to examine the extent to which certain characteristics of the grain, such as vitreousness and hardness, can be relied upon to indicate quality. It will be seen that very few genuinely hard or vitreous samples are included in the data, though, in these respects, they are, of course, typical of the commercial wheat grown in this State. The samples were first classified into three groups—vitreous, semi-vitreous, and mealy—and their Test Numbers are compared in Table XII., which gives the average, highest, and lowest test for each group of each of five varieties. It will be seen that there is evidence of but the slightest association of vitreousness and quality, and so many of the more vitreous samples show low tests and *vice versa*, that this property of the grain must be considered almost useless as an indication of their quality. They were then reclassified according to hardness (Table XIII.) which was estimated by the usual biting test, the classification being based on the combined opinions of two, and in some cases three, persons. It is evident that they show no association between hardness and quality. To some extent these results were surprising: it was thought that such tests did permit of broad distinctions being made; but these results, based as they are on such extensive and representative samples, must raise grave doubts as to the value of the tests, at least for average samples in which large differences do not occur.

(*b*) The Ford Lines.

From several of the Ford plants (Table II.) enough grain was available to permit of protein content determinations being made. Having the Test Number and protein content, the Specific Gluten Quality was calculated—by dividing the Test Number by the protein content—and, incidentally, the average weight of 20-grain samples was obtained. These results are given in Table III., from which it appears that the quantity of protein bears little, if any, relation to the Test Number, but that the Test Number and Specific Quality are closely related. Further, both these attributes seem to be definitely linked with small grain size.

Since these lines were grown side by side in a small plot, there is little possibility of normal relationships being upset by differences in environment or other conditions. The correlation coefficients between each pair of the factors were calculated, treating them as a group of 27 plants that might have been taken from any crop, and the results are tabulated in Table IV.

In these samples the protein content and Test Number show no correlation (+ .04), that is, an increase in protein content is as likely to be associated with a decrease as an increase in Test Number. Specific Quality shows only a slight (+ .20) tendency to increase as protein content increases, but there is a distinct tendency (— .36) for the percentage of protein to decrease as the size of the grain increases.

The Test Number shows a remarkably close correlation (+ .99) with the Specific Gluten Quality, though this result is misleading to some extent, because the Test Number is the dividend in the calculation of Specific Quality.* However, it may be concluded that nothing was gained by determining the protein content of these samples, and that the Test Number itself might have been taken as an indication of relative Specific Gluten Quality. When one considers the probable variations in protein content and Test Number in the population arising from most crosses in comparison with each other, it is obvious that the division of the Test Number by the percentage of protein cannot materially alter the order of the individuals. For material of this nature, then, the extra work involved in determining Specific Quality is not justified; it is sufficiently well indicated by the Test Number for practical purposes.

Considered in conjunction with the odds quoted below the Table, the correlation (— .72) between Test Number and grain weight is really high, and indicates a definite association of high "quality" with small grain. If the variations in protein content are eliminated the partial correlation coefficient becomes — .76, and if the material is treated as representing 11 lines of Ford (taking averages for the plants of a line) the coefficient is — .73, though the significance of this is less (about 100 : 1) owing to the smaller number of comparisons involved. These results would seem to indicate that, for the variety Ford, good quality will be found in small grained lines far more frequently than in large grained ones. All these lines have been planted, and an examination of the grain they produce will provide a check on this observation.

It cannot be inferred, of course, that small grain and quality will be associated in like degree in other varieties; indeed, the reverse might well be of just as frequent occurrence; but its probable value in selection appears to justify an inquiry as to whether a relationship of this nature can be shown to be at all common. No further pure line material—in which this possibility could be examined—was available here. On examining the commercial samples (Table I.) of Nabawa and Sword—the only varieties providing sufficient comparable material—comparing equal numbers of specimens of the same degree of plumpness from each district, a slight but distinct tendency in the same direction was found. For this comparison it was necessary to assume, of course, that the differences measured were due mainly to strains within the varieties. It therefore appears possible that a relationship between grain size and quality may exist, at least in certain varieties.

ACKNOWLEDGMENT.

I wish gratefully to acknowledge the interest and assistance of Mr. W. J. Spafford (Deputy Director) and the Agricultural Instructors in collecting the samples, an dolso of Mr. K. Woodroffe, R.D.A. (Cadet) who carried out many of the determinations.

*Cutler and Worzella (1933) have made the same observation. They repeatedly found an almost perfect positive correlation (+ .996) between "time" and "specific protein quality."

D

AGRICULTURAL EXPERIMENTS AT INMAN VALLEY.

EXPERIMENTS CONDUCTED ON THE PROPERTY OF Mr. A. M. FULLER.

[By R. C. SCOTT, Supervisor of Experimental Work.]

The experiments at Inman Valley consist of a series of tests with pasture varieties and variety mixtures. They were commenced in 1928 at the request of the local Agricultural Bureau and placed on the property of Mr. A. M. Fuller, who is keenly interested in such work.

Mr. Fuller's land is situated on the eastern side of the Inman Valley township, and this township lies midway between Victor Harbour and Yankalilla, or approximately 40 miles due south from Adelaide.

The plots themselves are placed on relatively flat land adjoining and on the northern side of the Inman River. It is on such land that the orange groves of this locality are generally to be found.

Close to the river the soil consists of somewhat silty material which drains rapidly and does not possess any appreciable natural fertility, but the hollows or the area adjacent to the hills is much heavier in nature, darker in colour, and has considerably higher fertility.

Originally the better quality land carried large redgum timber, whilst stringybark predominated on the poorer more sandy soils.

Rainfall at Inman Valley, 1928-1933.

Total	29·53	28·51	25·10	34·29	33·71	27·27	29·74

There is no official rainfall-recording station at Inman Valley, but since the commencement of the experiment a gauge has been placed on the farm, and the amounts registered are shown in the preceding table.

It will be noticed that the mean annual fall for the six-year period approaches 30in., and thus it would appear that the district is fairly favourably situated for the development of pasture plants. However, examination of the monthly falls shows that for four months of the year, namely, November to March, the total precipitation only amounts to about 3½in., and, as this corresponds with the period of maximum temperatures, it is difficult for perennial plants to carry through unless they possess particularly deep-rooting habits and drought-resisting properties.

The necessity for these requirements of perennial plants is further illustrated by the fact that in three years out of the six under review not a single point has been registered for the whole of a calendar month, but, in addition to this, the daily rainfall readings show that at times these rainless periods have extended from seven to eight weeks. Consequently, whilst the total rainfall is satisfactory, the distribution is very irregular and drought conditions more or less exist during the summer months of the year. On the other hand, however, the locality is noted for its relatively cool summer weather, with the result that this shortage of rain is not so severe on plants as would be the case should both dry conditions and extreme temperatures regularly prevail. Another characteristic of the Inman Valley rainfall is the amount registered during the winter months and the continued dampness of the surface soil, thus creating favourable conditions for the rapid hatching and free development of the lucerne flea. In the majority of seasons the flea attack is very serious on the lower lying land, and this pest practically wipes out the less vigorous and smoother leaved legumes, whilst retarding the development of the more resistant type, such as Subterranean Clover.

Plot 1.

The area of this plot is approximately 4½ acres and the character of the soil varies from the heavy black coloured type to that of the lighter more sandy nature, which adjoins the river.

Seeding took place in May, 1928, but owing to unfavourable climatic conditions a good stand was not secured in that year, and a further planting was made in the following season. The varieties comprising the mixture were:—Perennial Rye Grass, Italian Rye Grass, Wimmera Rye Grass, White Clover, Alsike Clover.

The idea behind this mixture was that the Italian Rye Grass would provide the bulk of pasture in the first two seasons, during which time the perennials should become firmly established. Being a biennial it would then die out and allow for the expansion of the other plants seeded. In the event of summer conditions proving too severe for Perennial Rye Grass, the Wimmera would be available to replace it, whilst it was thought that the clovers would prove suitable for local conditions.

However, whilst fair grazing was secured in the earlier years, amounting to almost three sheep per acre in 1930, the plot proved a failure from the point of view of establishing a good pasture mixture, and was eventually ploughed up in 1933.

The lucerne flea were far too severe for the clovers, which made relatively weak growth, and after struggling for two or three seasons, with the combination of dry weather in the summer and lucerne flea in the winter, both varieties eventually disappeared.

The Italian Rye Grass answered the purpose for which it was sown, but the Perennial was not the truly persistent strain and died out completely in its fourth year. The Wimmera was patchy, and reseeding was affected in 1931 by a disastrous fire which swept through the district, including this plot, in January of that year. However, whilst the plot proved a failure, all the varieties included in the mixture should not be condemned on that account, and their relative value for the district will be discussed later on under the section dealing with Varieties.

Plot 2.

Quite a different pasture mixture is seeded in this plot, which is 7.18 acres in area. As was the case with the planting of Plot 1, seeding extended over two seasons, namely, 1928 and 1929, whilst Subterranean Clover was added in 1932. The following varieties were included:—*Phalaris tuberosa*, Cocksfoot, Timothy,

Meadow Fescue, Sheeps Burnet, Chicory, White Clover, Red Clover, Strawberry Clover, Subterranean Clover.

At the present time the fodder available does not comprise a general mixture of all the pasture varieties mentioned above. The Timothy and Meadow Fescue failed entirely. They both germinated fairly well, but rapidly died out.

Scattered plants of Sheeps Burnet, Chicory, Red Clover, and White Clover are to be found, but, generally speaking, do not contribute a great body of feed.

The Strawberry Clover has done fairly well, more especially on the damper land at the foot of the hills and provides palatable grazing.

Because of the relative failure of the clovers, it was decided to add Subterranean Clover in 1932, since it was known that this variety would do so well. Accordingly, 6lbs. of seed per acre was drilled in at the end of April of that year, but owing to the dry ground and other growth it was difficult to effect a good cover, with the result that much was lost through being consumed by birds, chiefly parrots. However, that which escaped has seeded itself down, and the Subterranean Clover stand is now steadily thickening itself up.

The outstanding pasture has been *Phalaris tuberosa*, which made strong growth right from the first season, especially on the areas previously covered by large trees or where timber had been burned. Each year the crowns have increased in size, with a corresponding increase in the quantity of fodder, and this variety now contributes really good grazing.

The Cocksfoot was also satisfactory for a time, but it was found that particularly in the lighter class of land many plants were pulled up by stock when grazing upon them, with the result that the stand has now been thinned out very considerably.

The carrying capacity of this pasture has been recorded, and, although sheep, cows, and horses have been depastured, the grazing has been calculated on a sheep per acre basis, allowing one horse as being equivalent to 10 sheep and one cow or light horse to eight sheep in amount of fodder consumed. The grazing year has been taken from April 1st to March 31st, and the results obtained are shown below:—

1928-29	1.12	sheep	per acre	per annum
1929-30	2.14	"	"	"
1930-31	2.52	"	"	"
1931-32	2.79	"	"	"
1932-33	2.91	"	"	"
Mean for five years	2.30			

The above figures show a steady improvement in quantity of pasture obtained, and it is reasonable to assume that such improvement will be continued as the Subterranean Clover becomes better established and the *Phalaris tuberosa* crowns expand over a wider area.

There is little doubt that ultimately a really good pasture will be secured, but of a much different nature to that aimed at when the original seeding was planned.

From the experience gained with this plot, it would appear advisable to confine the mixture to two varieties, namely, *Phalaris tuberosa* and Subterranean Clover.

The former should be firmly established before any attempt is made to provide a dense mat of the latter, and in this connection the land should be thoroughly prepared and 4lbs. to 5lbs. of *Phalaris tuberosa* seed planted per acre, together with a sprinkling of Subterranean Clover.

On the other hand, the former could be sown alone, and a heavier seeding of the latter made in the second year, thus avoiding the danger of crowding out the Phalaris plants which are very delicate in the first few weeks after germination.

PLOT 3.

In 1930 it was decided to make a comparison between the two perennial grasses which appeared best suited to the district, namely, Perennial Rye Grass and *Phalaris tuberosa*. Accordingly, a small field, approximately 1½ acres in area, was sown with these varieties in 1930.

In earlier years the land selected had carried fruit trees, chiefly oranges and apples, but owing to lack of attention many of these had failed, and in 1928 and 1929 potatoes, melons, and pumpkins were planted.

In May of 1930 the soil was well prepared and one-half of the field sown with *Phalaris tuberosa* at the rate of 8lbs. of seed per acre, and the remaining half with 30lbs. of Perennial Rye Grass seed per acre.

At the time, Certified Rye Grass seed was difficult to obtain, and eventually uncertified New Zealand seed was purchased. Consequently there was no guarantee that such seed had been harvested from an old pasture stand and possessed truly perennial habits.

In the first year an excellent stand was secured, resulting in the production of a bulk of pasture. Again in the second year really good grazing was obtained, but in 1932, that is to say, in the third season after planting, it thinned out very appreciably, and at the present time only scattered plants are to be found.

This plot has provided an excellent illustration of the importance of good seed. That planted here was of the sort-lived type, growing strongly at first, but dying out in the course of a few years.

On the other hand, seed of the best type would have yielded leafy plants which, with normal seasonal conditions, would have survived for a considerable period of time.

However, it does not follow that seed possessing these desirable characters can only be secured through some certification scheme, since in the Inman Valley district and a number of other places in South Australia there are limited areas which were planted with good type seed many years ago. The plants present to-day are of good pasture quality, are truly perennial, and well suited to the soil and climatic conditions of the district. Therefore, seed secured from such crops would be very valuable for planting under similar conditions. Failing this, however, certified seed should be purchased, as it is false economy to purchase cheap lines, which eventually may not meet requirements.

Notwithstanding the results obtained from this plot, there are good stands of rye grass in the locality, and there is little doubt that, provided that seed of good strain is planted, Perennial Rye grass is well suited to the damper areas of the Inman Valley district.

The *Phalaris tuberosa* was rather slow growing at first, but contrary to the experience with the Perennial Rye Grass steadily improved with age, and now provides really good pasture.

However, the plants are somewhat crowded, and the seeding of 8lbs. per acre could, with advantage, be reduced to approximately half that quantity. This would allow for full development of the crowns of the plants and quicker recovery after grazing than is the case when they are crowded too closely together.

The grazing returns taken over the full area, including both plots, have been kept, and have been maintained, at a fairly even figure, being 4.68 sheep per acre in 1930, 4.33 in 1931, and 5.01 in 1932. This regularity is due to the fact that, whilst Phalaris has improved, the Rye Grass has slipped back in the amount of fodder produced. Owing to the strain of Rye Grass seeded, the results secured from this test do not permit a comparison of the varieties to be made. However, both are capable of satisfactory returns under special circumstances, but it would appear that *Phalaris tuberosa* has the ability to thrive and yield good pasture when seeded in poorer quality soil and drier conditions than would be suitable for Perennial Rye Grass.

Variety Plots.

A number of varieties were tested, each being sown as a pure stand in plots about one-sixth of an acre in area. Relatively few showed to special advantage, and the pastures of importance in this district appear to be limited in number.

There is little doubt that Subterranean is the best variety of clover, although Clustered has also made fair growth. The only other worthy of mention is Strawberry Clover, which has spread along the edge of a watercourse and provided palatable grazing.

In connection with the clovers, it should be recalled that lucerne flea render very difficult the establishing of any weak-growing legume.

Amongst the grasses, *Phalaris tuberosa* has yielded most fodder.

Wimmera Rye Grass also has value for the lighter and drier soils, whilst Perennial Rye Grass requires wetter and richer soil conditions.

A plot of Wallaby Grass (*Danthonia pilosa*) was included in the trials, and, although this variety made little headway in the first season, it has since done well and is worthy of inclusion in a pasture mixture.

Cocksfoot is another fodder which promised fairly well, but did not survive as well as anticipated.

Acknowledgment.

It is desired to place on record our appreciation of the co-operation of Mr. A. M. Fuller in these experiments and the manner in which he has kept the grazing and observation records required. The local Agricultural Bureau has also organised visits of inspection, and to all concerned we extend the thanks of the Department.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to August 31st, 1934.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to July 31st, 1934.	No. Eggs Laid Month of August, 1934.	Total Eggs Laid April 1st, 1933, to August 31st, 1934.
No. 1 test	8,864	841	9,705
No. 2 test	8,237	677	8,914
No. 3 test	7,856	761	8,617
No. 4 test	9,238	727	9,965
No. 5 test	4,217	584	4,801

AGRICULTURAL BUREAU CONFERENCES.

SOUTHERN CONFERENCE.

There was a large attendance of members at the Southern Conference at Strathalbyn on August 16th. Mr. C. M. Hudd presided and the Branches represented were Ashbourne, Belvidere, Blackheath, Brinkley, Currency Creek, Echunga, Finniss, Hartley, Inman Valley, Langhorne's Creek, Milang, Mount Compass, Murray Bridge, Narrung, Port Elliot, Strathalbyn, and Yundi.

Officers present were Messrs. A. J. Cooke (Chairman of the Advisory Board of Agriculture, who delivered the opening address), W. J. Spafford (Deputy Director of Agriculture), C. F. Anderson (Poultry Expert), H. B. Barlow (Chief Dairy Instructor), H. H. Orchard (District Horticultural Instructor), A. H. Robin Veterinary Officer of the Stock and Brands Department), C. A. Goddard (Assistant Wool Instructor to the School of Mines), and H. C. Pritchard (General Secretary Agricultural Bureau). Mr. F. W. Allison acted as local Secretary.

In his opening address Mr. Cooke made special reference to the agricultural conditions of South Australia, which on account of the recent rains were more hopeful than appeared previously. Fluctuations in the price of wheat due to indifferent seasonal characteristics in countries where wheat was grown promised better prospects in the wheat industry than had been expected for some time. In regard to other lines of production, such as dairying and poultry raising, the conditions were a little better than they were last year. At the time of the Conference, legislation had not been passed in South Australia for the marketing of dairy produce, and prices were lower than applied to the other States. Whatever legislation was adopted, it was hoped that farmers would at least get the same advantages under a State scheme as they would under the Federal Act. He had no brief for either scheme, but he was of the opinion that in a season of plenty, with large exports, the Federal scheme would be better, but with a lean season, with little export surplus, the proposed State scheme would probably be more advantageous to the farmer. The outlook for the poultry industry, too, was better than last year. The export season had opened well, and he thought that the prices would be equal if not higher than the previous season.

Papers were read by Mr. A. H. Paterson (Strathalbyn), on "Farm Management"; Mr. G. Sissons (Strathalbyn), "Almond Growing"; Mr. D. J. Turvey (Milang), "Care and Management of the Poultry Yard"; Mr. B. St. J. Proctor (Mount Compass), "Some Remarks on the Characteristics, Classification, and Marketing of Wool."

In addition to assisting in discussions on the papers, officers of the Department replied to questions on the following subjects:—The best stages to cut meadow hay and the best method of manufacture, the low quality of wheats grown in South Australia, the best breed of ram for fat lamb raising, the symptoms of bot flies and blood worms and treatment, cure for chronic greasy heel in draught horses, the best method of marking lambs, treatment of impotent bulls, treatment of sows at farrowing time, the best treatment for a cow that has eaten wheat, and the use of strychnine in a poison bait.

It was decided to hold the next Conference at Mount Compass.

After a short discussion on licensing veterinary surgeons, it was resolved that the Congress Committee be requested to include the question of the appointment of veterinary officers for country districts on the Congress agenda.

In the evening delegates attended the public meeting convened to hear Mr. C. F. G. McCann (Trade Commissioner for South Australia) speak on "Products for Overseas Markets."

AGRICULTURAL BUREAU CONFERENCE AT COROMANDEL VALLEY.

The Annual Conference of Hills Branches was held at Coromandel Valley on Thursday, August 23rd, 1934, under the auspices of the Blackwood Branch. Mr. J. Turner occupied the chair. Delegates were present from Branches situated at Clarendon, Blackwood, Lenswood and Forest Range, Gumeracha, Cherry Gardens, Scott's Bottom, Ironbank, Balhannah, and Longwood. The Department of Agriculture was represented by Messrs. W. J. Spafford (Deputy Director of Agriculture), G. Quinn (Chief Horticultural Instructor), R. Fowler (Manager Government Experimental Orchard), H. H. Orchard (District Horticultural Instructor), and H. C. Pritchard (General Secretary Agricultural Bureau).

Mr. H. N. Wicks (Advisory Board of Agriculture) delivered the opening address. He stressed the necessity for growers to eliminate anything but the best fruit and of the best varieties, if they were to retain their place on overseas markets. A great many varieties of very little value were now being grown, and these must be replaced by good varieties. Cheaper production methods should also be attempted. This could be achieved by such means as the combining of sprays, also the use of power machines in orchards which were not large enough to provide paddocking for draught stock. The export variety list was far too large. Only those varieties which could be grown to perfection should be retained. In the knowledge of working over trees to new varieties Australia was very backward. There was a need for an institution to supply horticultural instruction, particularly in South Australia. Such an institution would educate orchardists in the best methods of carrying out the various orchard practices.

Papers were read by Mr. R. Fowler on the "Green Peach Aphis," and Mr. Max Vickers (Lenswood) on "Orchard Drainage"; and a paper supplied by Mr. W. A. Robinson (Gumeracha) on "The Care of the Lambing Flock." Numerous questions were answered by Messrs. Quinn, Spafford, and Fowler, and the following resolutions were passed:—"That this Conference affirms other resolutions asking for the enforcement of the Insecticides Act provisions which demand that the analysis of the contents be printed on the container"; "That this Conference supports the Bill now before Parliament which provides for grade standards, so that the sale of poor quality fruit be prohibited"; "That all Fruit Inspectors be more strict in enforcing the law regarding unsprayed orchards"; "That legislation be enacted to have the time set out on weighbridge cartnotes, *i.e.*, the time when the load is weighed, and also to have deleted from cartnotes the name whom the goods are for"; "That the Pure Foods Regulations relating to vinegar be enforced"; "That the Government be asked to make the services of a veterinary surgeon available to producers, under the control of the Department of Agriculture." It was decided to hold the next Conference at Lenswood. During the day a Life Membership Certificate was presented to Mr. A. K. Ashby, of Blackwood, by Mr. W. L. Summers.

CONFERENCES ON EYRE'S PENINSULA.

Branches of the Agricultural Bureau held two Conferences on Eyre's Peninsula at Yeelanna and Kyancutta, on September 5th and 9th respectively. The Department of Agriculture was represented by Messrs. A. J. A. Koch (Advisory Board of Agriculture), W. J. Spafford (Deputy Director of Agriculture), H. B. Barlow (Chief Dairy Instructor), H. D. Adams and W. H. Brownrigg (Agricultural Instructors), and H. C. Pritchard (General Secretary).

YEELANNA.

When opening the conference at Yeelanna, Mr. Koch congratulated the members on the splendid condition of their crops this year, and he considered that the seasonal prospects were with Eyre's Peninsula. He had associations many years ago with the districtc and he now found that what was once a wilderness was now studded with attractive and prosperous-looking farms. Because of their zeal to convert mallee areas into smiling farms in the past, the mallee farmer had been inclined towards over-expenditure. Farmers generally had taken a short view and had not planned their work sufficiently far ahead. There was a tendency to finance the farm from year to year without looking into the future. The farmer should strive to reach his objective over a period of time, and arrange his finances accordingly. Further, there was a need for the farmer to be a manager rather than a farm worker. If he looked upon the complete control of a farm as a one-man job, it was doubtful if he could give the farm as much attention as it deserved. The experience of years should be used to multiply the departments of the holding, which should be as much a factory as a farm. While wheat, oats and barley could not be made profitable at present prices by direct selling, means should be found to market these products through eggs, sheep, bacon, &c.

The following papers were read by members:—"Seed Wheat," Mr. R. R. Wilson (Yeelanna); "Better Wheat Marketing Methods," Mr. E. A. Pfeiffer (Cummins); "Stabilising the Wheat Industry," Mr. G. A. Vigar (Mount Hope); "Care of Farm Machinery," Mr. W. E. Bryant (Cummins); "Tomato Growing in the Open for Cummins and Yeelanna Districts," Mr. R. Granit (Cummins); "Some Aspects of Mortality among Sheep from eating Stinkwort," Mr. M. T. Gardner (Koppio). Questions were answered by Departmental Officers on subjects such quality in South Australian wheats, encouraging stock to eat ensilage, the control of takeall, the control of salt patches, the treatment to stimulate grass and cereals, the origin of drake in crabhole country, the germination of wild oats, and the control of blowflies.

The following resolutions were carried:—"That the Advisory Board confer with the wheat merchants with a view to amending the present system of buying wheat and docking for second-hand bags or refusing same, and asking that agents be granted power to use discretion in accepting wheat delivered in good, sound bags." "That the tariff on farming implements be reduced considerably." "That the sales tax on lubricating oils and greases used in the production of power by primary producers be abolished." "That further funds sufficient for developmental needs be made available for construction of roads in newer settled areas north and west of the hundred of Koppio." "That all discounts available to Farmers Assistance Board, be credited to applicants under Assistance, instead of as at present retained by the Board." "That this Conference asks the Advisory Board to ask the superphosphate manufacturers for a reduction of 5 per cent. for cash on purchase price of super." "That the next Conference be held at Cummins."

Mr. H. B. Barlow addressed the evening session on the Dairying Industry.

PIGKEEPING.

The Library of the Department of Agriculture has received from the Ministry of Agriculture, England, a copy of Bulletin No. 32, "Pig-Keeping," 62 pages, prepared by W. A. Stewart, M.A., B.Sc., Principal of the Moulton Farm Institute, Northampton. Separate chapters deal with breeding, feeding, pigsties, open air pig-keeping, pig-keeping, &c., as well as a number of plans of sties and pig rearing houses together with illustrations of the types of pig required by the English market are included in this most useful bulletin. The London price of the Bulletin is 1s. 6d. net.

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 8.—THE PURPLE-STEMMED OR HORNY THORN APPLE.

Datura Tatula, L.

The Thorn Apples are solanaceous plants belonging to the genus *Datura,* of which there are some twelve or more species widely distributed throughout the tropical and temperate regions of both worlds. They are noted for their trumpet-shaped flowers and capsular fruits, the latter usually having an external covering of thorns or prickles, and liberating, when mature, large numbers of reniform compressed seeds. The flowers of some species are very large; for example, in the Angel's Trumpet, *Datura suaveolens,* a native of Mexico and often cultivated in gardens under the name *D. arborea,* the white pendulous blooms may be nine inches or more in length; in other species they are smaller, but only rarely are they less than two inches long, the colour being usually white or purple. All the species are more or less poisonous, due to their containing powerful alkaloids, and a number of them yield drugs of importance in medicine. *Datura Tatula,* the species here to be described, is probably only a varietal form of the common Thorn Apple, *Datura Stramonium,* L., a cosmopolitan weed, believed to be native to the shores of the Caspian Sea. There is some difference of opinion as to the native home of *D. Tatula*; according to some authorities it is of European or Asiatic origin, while others maintain that it is a native of tropical America. Both species, however, have been introduced into most temperate countries.

Relationship between Stramonium and Tatula.—*Datura Stramonium,* known as "Jamestown-weed" or "Jimson-weed" in the United States, is the best-known Thorn Apple. The drug Stramonium, which is widely used in the treatment of asthma, consists of the dried leaves of this plant. It resembles *D. Tatula* very closely both in structure and poisonous properties, the chief difference being one of colour; in Tatula there is a red or purple colouration of the stems and main leaf-veins, and the flowers are purple or pale blue, whereas in Stramonium the vegetative parts are green and the flowers white. There is also a slight difference in the fruit which, in both species, is an ovoid spiny capsule about as large as a walnut. The spines are all about the same length in Tatula, while they tend to become shorter towards the base in Stramonium. The two plants were originally described by Linnaeus as separate species, but it is probable that the one is merely a variety of the other; such indeed, is the view adopted in the Index Kewensis, in which *D. Tatula* is listed as a synonym for *D. Stramonium.* De Vries, in his great work, The Mutation Theory, points out that the gain or loss of a single character is not sufficient to justify the conferring of specific rank upon a given plant form, and inasmuch as variation is known to occur in the development of the spines on the fruits in both Stramonium and Tatula, it would seem that the colour difference is the only really constant character separating the two forms.

The production of red or purple sap, such as, for example, occurs in beetroot, and in the foliage of many garden plants, is a phenomenon of widespread occurrence in the vegetable kingdom. These pigments are called anthocyanins, and they differ from other plant pigments in being dissolved in the watery sap of the cells, instead of being contained within definite corpuscles. Anthocyanins are commonly found in seedlings and young developing shoots, especially during cold weather. For instance the leaflets of young plants of the white clover (*Trifolium repens*) often show a bright red colouration of the main veins during winter months. The full significance of this anthocyanin formation is not known, but physiologists are agreed that it is bound up in some way with the conditions of temperature and illumination to which the plants are subjected. On the other

hand the capacity to form anthocyanins under a given set of conditions is part of the native constitution of a plant, and as such is transmitted in accordance with the rules governing the inheritance of other characters. Such tendencies may arise, or become more pronounced, by mutation, and lead to abnormal colouring of foliage and other parts usually green, and so to the production of forms with an ornamental value. By applying the methods of breeding and selection to such forms horticulturalists have produced a multitude of ornamental plants greatly prized by the public on account of their red or purple, but none the less abnormal, colours. It is this capacity to form anthocyanins that distinguishes *Datura Tatula* from *D. Stramonium*, and accounts for the purple flowers and red stems and leaf-veins of the former plant. When the two forms are crossed the resulting F.1. plants have red stems and purple flowers, the colour being, however, less intense than in the Tatula parent; in the following or F.2. generation there is evidence of typical Mendelian segregation into Tatula, Stramonium, and forms similar to the F.1. generation. De Vries regards Tatula as the older of the two, the Stramonium form having arisen by variation in the direction of *albinism*, or *loss* of the capacity to form anthocyanin; according to this conception Stramonium is a variety of Tatula, instead of the latter being one of Stramonium. It is worthy of note that the Indian species, *Datura fastuosa*, has both purple-flowered and white-flowered forms, the former being regarded as the type, while the latter is distinguished as the variety *alba*. In view of the uncertainty as to the correct botanical name to be given to this plant, the present article retains the specific rank of Tatula as a matter of convenience. Moreover, it is shorter to write *D. Tatula* than *D. Stramonium* var. *Tatula*.

Confusion with the Castor Oil Plant.—The dry summer conditions which obtain throughout the greater part of this State are not very favourable to the growth of the Thorn Apple. When gathered the plants wilt very quickly, and while an occasional specimen is seen growing on the roadside, the Thorn Apple prefers sheltered situations, and is to be found most often along the banks of rivers and creeks, where shade and moisture are obtainable. Another plant which thrives under precisely similar conditions is the Castor Oil Plant, *Ricinus communis*, L. This also bears spiny fruits, and Datura is, as a consequence, often confused with it. Both plants have a peculiar, rather sickly, but readily distinguishable odour, and a reddish colouration of the leaves, more uniform than in Datura, is extremely common in Ricinus. But beyond this point all resemblance ends. The Castor Oil Plant, in the first place, grows to the size of a small tree, and it bears very large leaves which are almost circular in outline, but palmately divided into triangular serrate lobes; the Thorn Apple, on the other hand, is merely a herb and is rarely above five feet high; it bears ovate leaves which are sinuate-toothed, and though some are large, usually they are considerably smaller than those of Ricinus. Then, the flowers and fruits of Ricinus are crowded together in a conspicuous raceme-like inflorescence, whereas those of Datura are borne singly in the forks of the branches. Again the spiny fruit of the Castor Oil Plant is globular in shape and only about half the size of that of the Thorn Apple; when mature is breaks up into three portions, each containing a single seed about as large as a grain of corn; the larger ovoid fruit of Datura bursts by separation of its outer walls in the manner shown in the accompanying plate (Fig. C.), and sets free the very numerous seeds, each one many times smaller than a Castor Oil seed. Finally, though the seeds of the Castor Oil Plant are poisonous, the rest of the plant is harmless enough and is readily eaten by stock, while the entire plant of Thorn Apple is poisonous, and is usually left alone by grazing animals.

Botanical Name and Classification.—The words *Datura* and *Tatula* are really one and the same. Both are derived indirectly from the Sanscrit *dhustura* or *dhattura*, words meaning "insane" and applied as names to certain species of the genus. The poisonous properties of the plants were well-known to the ancients,

and the names were doubtless in allusion to the symptoms of wild delirium produced. The Arabic equivalent is *tatorah*. *Datura* comes through the modern Indian name *dhatura*; *Tatula* is said to be the Turkish corruption of *dhatura*, through the Persian.

The Daturas belong to the *Solanaceae* or Nightshade family, which is the one including the Apple of Sodom (*Solanum sodomaeum*), of which an account was given (in Article No. 4. of this series) in the issue of this *Journal* of March 1934. Mention was there made of the more important solanaceous plants growing in this State, and a description was given of the characters of the family, all of which are well shown by the genus *Datura*.

The Genus Datura.—*Datura* is readily distinguished from other genera of *Solanaceae* by a number of characters. Firstly, the flower has a five-toothed calyx which is usually more or less inflated; and it subsequently separates transversely so as to leave a collar around the base of the thorny fruit. The corolla is trumpet-shaped, consisting of a long tube and an expanded limb, the latter being folded in the bud. The stamens are enclosed within the corolla-tube, the slender anthers opening lengthwise, and not by terminal pores as in *Solanum*. The fruit is a capsule, opening septifragally at the summit by four valves, the very numerous seeds being compressed, rather small, reniform, and somewhat wrinkled.

The number of species given by different authorities varies from 12 to about 25. The species are widely distributed throughout temperate and tropical parts of Europe, Asia, and America. One species, *D. Leichhardtii* is native to Australia, and occurs in the Northern parts of this State. The classification into species presents considerable difficulties owing to the many varietal forms growing in certain countries, particularly in India where the Daturas have been and are still to some extent cultivated. G. Watt, in the Dictionary of the Economic Products of India, remarks that many peculiar forms are probably escapes from a former cultivation; that in many Indian localities the plants are only semi-wild, and have all the appearance of a degenerated offspring of a cultivated stock, once more generally cared for than that of the present day.

Description of D. Tatula.—An erect annual, 1-5ft. high, glabrous or the young parts sparingly pubescent, the stems and main leaf-veins reddish-purple. Leaves thin, ovate in outline, acuminate at the apex, mostly narrowed at the base, 3-8in. long, irregularly sinuate-lobed, the lobes acute, petioles 1-4ins. long. Flowers pale-purple or blue, solitary on short terminal peduncles arising between the forks of the branches, and remaining erect in the fruit; calyx prismatic, less than half the length of the corolla; corolla about 4in. long, the limb 1½-2in. in diameter when expanded. Capsule erect, ovoid, about 2in. long, thickly clothed with prickles which are not noticeably shorter at the base. In flower, most of the year.

Properties.—The poisonous nature of the Daturas is due to the presence in all parts of the plants of an alkaloid hyoscyamine, together with varying amounts of the isomeric, and perhaps better known substance, atropine, the mixture of the two being sometimes referred to as daturine. Chemically hyoscyamine is an ethereal salt, and consists of an alkaloid *tropine*, which is both a nitrogenous base and an alcohol, in combination with an aromatic acid, *tropic acid*. The compound exists in two forms, a "right-handed" or dextro-rotatory, and a "left-handed" or laevo-rotatory form. Hyoscyamine proper is the "left-handed" or laevo-form; atropine is a mixture of equal parts of the two forms. Since the "right-handed" or dextro-form is relatively inactive physiologically, both atropine and hyoscyamine are, from a physiological point of view, similar, the former being, however, somewhat weaker and so relatively less active than the latter.

Thus the symptoms of poisoning by Stramonium and other species of *Datura* are essentially similar to those due to Belladonna, and other substances containing atropine. The same alkaloids occur in a number of solanaceous plants, though the proportions vary, and the resulting symptoms may be complicated by the presence of varying amounts of other alkaloids as well.

The dominant action of atropine and hyoscyamine is to depress the activity of nerve endings, and so to prevent the proper functioning of tissues and organs controlled by the nerves concerned. Thus the salivary and sweat glands are paralysed, causing dryness of the mouth, intense thirst, difficulty in swallowing, and dryness of the skin. The pupil of the eye is widely dilated, and accommodation is paralysed, due to the action of the poison on the ends of the main nerve supplying the eye-muscles. Then there is a rapid acceleration of the pulse due

Thorn Apple. Photograph showing branching habit (see coloured plate opposite).

to interference with the "braking mechanism" of the heart-beat, that is to say, to paralysis of the ends of nerves whose normal function is to slow down the heart-beat. Again, there is relaxation of the muscular coats of the bronchial tubes in the lungs, due to paralysis of the ends of nerves supplying these muscles—hence the value of the drug in the treatment of asthma. Then again there is flushing of the face and other parts of the skin, due probably in the first instance to relaxation of the muscular walls and hence to dilatation of the smaller blood-vessels, though the same effect is later due to a depressant action on that part of the brain which regulates blood pressure.

THE PURPLE-STEMMED THORN APPLE (*Datura Tatula L.*).

About a third natural size.

A.—Flower laid open to show the arrangement of the five stamens and pistil.

B. —The fruit in transverse section.

C —The fruit, showing the leathery pericarp, dehiscing by four valves.

In addition to such peripheral effects due to action of the poison on the ends of nerves remote from the brain and spinal cord, atropine and hyoscyamine act centrally on the brain itself. The most noticeable effect is upon the higher brain centres, these being strongly excited, causing prolonged delirium, the symptoms sometimes resembling those of delirium tremens or acute mania. The poison also first stimulates and then depresses those centres in the brain which control the pulse, the blood-pressure, and respiration. Death, when it occurs, is usually due to heart failure combined with asphyxia due to depression of respiration. If recovery takes place the patient may have no recollection of his illness..

Uses.—The only uses of the plants are those connected with their poisonous properties, and may be classed as medical and criminal. As regards the former, the chief use of Stramonium is in cases of asthma, for which it is particularly valuable, the drug being taken either internally, or else by smoking cigarettes made from the dried leaves. Strangely enough, this use of the plant seems to be relatively modern. It was probably not known to the Romans, in fact, it is doubtful whether the plant was used at all in Roman medicine. On the other hand there is evidence for believing that the poisonous properties of the Daturas were well-known to the ancient inhabitants of India, and that the use of these plants for both medicinal and criminal purposes goes back to remote antiquity. The seeds of *Datura Tatula* and *D. Metel* are stated to have been used to produce frenzied ravings by priests in Delphic and some other temples, and those of *D. sanguinea* are said to have been used for a similar purpose in Peru. In India the Daturas are used for many purposes where Belladonna would probably be employed in the west. Datura seeds are regarded by the Indians as a cure for hydrophobia, and are used by them medicinally in the treatment of mania, convulsions, and epilepsy, which usage suggests the homæopathic dictum, *similia similibus curantur.*

As regards criminal uses, the seeds of *D. fastuosa* and other species are known to enter into the composition of certain alcoholic beverages which render the consumers literally mad. By this and other means the poisons are used in India, not only for purposes of murder, but also for stupefying victims with a view to robbery. Accounts given of these practices, written in the sixteenth century, are said to be just as true of India to-day as at the time they were written. Some of the descriptions are quaint and amusing to read, but they reveal, on the part of the natives, an astonishingly accurate knowledge of the drug and its effects upon the prospective victims. The following, which is taken from G. Watt's Dictionary of the Economic Products of India, is part of an account, published in 1596, of a Voyage to India by Huyghen van Linschoten, the plant concerned in this case being probably *D. fastuosa.*

> "They have likewise an hearbe called Deutroa which beareth a seed, whereof bruising out the sap they put into a cup or other vessel and give it to their husbands, eyther in meate or drinke and presently therewith, the man is as though hee were halfe out of his wits, and without feeling, or else drunke (doing nothing but) laugh, and sometimes it taketh him sleeping (whereby he lieth) like a dead man. . . . In which sort he continueth foure and twentie hours long, but if they wash his feete with colde water hee presently reviveth and knoweth nothing thereof but thinketh he had slept."

Eradication.—The Thorn Apple does not offer a difficult problem of eradication. In most situations the plants are not numerous, though dense infestations are sometimes found along river banks. The plants should be uprooted whenever found, and, if seed capsules are present, should, if possible, be piled in heaps and burnt.

STATE OF SOUTH AUSTRALIA.

SUMMARY OF LIVESTOCK STATISTICS, YEAR 1933.

[By W. L. JOHNSTON, Government Statist.]

I. SHEEP AND WOOL.

1. *Number of Sheep.*—The sheep flocks on December 31st, 1933, numbered 7,941,060, exceeding the record of 7,713,236 in 1932, the next highest being 7,646,239 in 1891. Compared with 1932, there was an increase of 227,824. The flocks were classified as follows:—Ewes, 4,073,611 (3,815,513); wethers, 2,079,515 (1,788,094); rams, 100,169 (97,858). Under one year old, 1,687,765 (2,011,771).

2. *Breeds of Sheep.*—86.6 (86.7) per cent. of the flock were returned as pure-bred Merino and 5.9 (5.3) per cent. Merino comebacks; 1.4 (1.0) per cent. other pure breeds (Corriedale, Shropshire, Dorset Horn, Lincoln, Romney Marsh, Southdown, Suffolk, etc.), and 6.1 (7.0) per cent. crossbreds.

3. *Lambing,* 1933.—During 1933 3,304,532 (3,127,432) ewes were mated and 2,051,130 (2,270,081) lambs marked; percentage, 62.07 (72.59).

4. *Winter Lambing,* 1934.—3,480,000 ewes were reported as either mated or intended to be mated for the winter lambing of 1934. In addition 110,000 ewes were expected to be reserved for spring lambing. Details for the 1934 winter lambing, which has naturally been affected by the dry spell, are now being obtained and will be published later.

5. *Wool Clip.*—8,111,296 (7,573,237) sheep and lambs were shorn, the total clip including locks, bellies, pieces, &c., being 67,668,282 (65,154,632) lbs.; increase 2,513,650lbs. The average fleece for sheep and lambs combined was 8.34 (8.60) and for sheep only 9.81 (10.42) lbs.

6. *Total Wool Production.*—Subject to slight revision, it is estimated that the grand total wool production, including the clip and wool fellmongered and wool on local skins exported, was 79,500,000 (75,727,946) lbs.; increase, 3,772,054lbs., value £4,625,000 (2,309,702); increase, £2,315,298; the average value per lb. greasy being 13.96d. (7.32d.).

II. CATTLE.

1. *Numbers.*—All kinds, 352,728 (312,932); increase, 39,796. Dairying cattle, 163,875 (149,172); increase, 14,703, classified as follows:—In milk, 110,551 (101,974); dry, 36,930 (29,508); and heifers springing, 16,394 (17,690). In addition there were 22,211 (18,129) other heifers one year and over, which are possible additions to the dairying herds. The dairy cattle number was a record, and total cattle highest since 1925.

2. *Butter and Cheese.*—Provisional 1933-34 butter, 19,700,000lbs. and cheese, 5,130,000lbs., have only been exceeded by the previous year's production of 21,310,006 and 6,093,170lbs. Overseas exports were:—Butter, 8,308,420 (9,500,027) lbs.; cheese, 667,172 (1,578,780) lbs.

III. HORSES, 196,789 (190,222); increase, 6,567, being highest since 1928.

IV. PIGS, 91,573 (113,831); decrease, 22,258.

V. GOYDER'S LINE OF RAINFALL AND LIVESTOCK.

During the year 1933 the percentage to the total of sheep outside Goyder's Line of Rainfall decreased from 37.72 to 34.30; cattle increased 28.51 to 29.30; and horses 26.81 to 27.59. The numbers within and without the line for 1933 were sheep 5,217,669 and 2,723,391, cattle 249,387 and 103,341, horses 142,490 and 54,299.

VI. Interstate Movement of Stock.

The State gained 27,604 head of cattle, 265,297 sheep, and 2,011 horses by transit of stock between States. The total interstate imports were sheep 320,121, cattle 39,684, horses 3,540, and export sheep 54,824, cattle 12,080, horses 1,529. Net exports of horses to overseas countries 245.

VII. Slaughtering.

Sheep and lambs, 1,495,127 (1,279,245); cattle, 104,488 (89,350); pigs, 167,526 (150,318). For the year ended June, 1934, 216,535 (53,863) carcasses of lambs were exported and 746,884 (193,055) lbs. of pork.

VIII. Value of Pastoral and Dairying Industries.

Provisional for 1933-34, £7,100,000 (£4,744,161); increase £2,355,839.

1. Livestock as at December 31st, 1933, in Comparison with December 31st, 1932.

Grand Total Wool Production (clip, fellmongered, and on skins exported), subject to slight revision, 1932-33, 75,727,946lbs.; 1933, 79,500,000lbs.: increase, 3,772,054lbs.

Minus sign denotes decrease.

WHEAT PRODUCTIVITY CLASSIFICATION, 1933-34.

With a view to ascertaining the extent of acreage producing very high and very low returns of wheat per acre, all wheat farms have been classified according to their productivity per acre. The accompanying return sets forth comparative details for the three seasons 1931-32, 1932-33, and 1933-34.

The total yield for 1933-34 was 35,373,466 (42,429,614) bushels, averaging 9·26 (10·43) bushels per acre, and the Agricultural Areas Rainfall, April-November, was 11·66 (14·70) inches.

Of the 13,919 (14,248) farms in the State, 7,192 (8,267), or 52 per cent. (58 per cent.) harvested yields of 9bush. and over, and 6,727 (5,981), or 48 per cent. (42 per cent.) yields of less than 9bush.; 2,649 (2,323) farmers, or 19·03 (16·30) per cent. harvested 18bush. per acre and upwards, producing 33·21 (26·38) per cent. of the crop from 13·60 (12·92) per cent. of the total area sown; 32·64 (41·72) per cent. of the farmers harvested 9bush. and under 18bush., and 48·33 (41·98) per cent. less than 9bush. per acre.

Of the 2,649 (2,323) farms with average yields of 18bush. and over, 1,182 (940) were in the Central Division, 1,067 (967) in the Lower North, and only 400 (416) in the remaining four Divisions of the State.

Of the total of 6,727 (5,981) farms under 9bush., the Murray Mallee and Western Divisions had 1,956 (2,064) and 2,116 (1,643) respectively. In these Divisions there were 733 and 519 under 3bush., 767 and 922 with 3-6bush., 456 and 675 with 6-9bush., and 388 and 511 with 9bush. and over.

During the last 10 seasons the total State acreage under wheat for grain has increased to 1,400,000, of which 1,000,000 acres have been in these two Divisions, and the effect has been to reduce the average yield for the State.

The following are the details in Divisions :—

Divisions.	Wheat Crop.		Wheat Farms with Yields of			
	Total.	Average per Acre.	Under 9 bush.	9-18 bush.	18bush. and over.	Total.
	Bush.	Bush.	No.	No.	No.	No.
Central	7,943,937	15·85	1,032	1,834	1,182	4,048
Lower North	12,689,577	14·79	705	1,379	1,067	3,151
Upper North	2,399,603	6·61	834	351	142	1,327
South-Eastern	712,988	16·14	84	126	212	422
Western	6,899,363	6·21	2,116	472	39	2,627
Murray Mallee	4,727,998	5·42	1,956	381	7	2,344
Total 1933-34	35,373,466	9·26	6,727	4,543	2,649	13,919
1932-33	42,429,614	10·43	5,981	5,944	2,323	14,248
1931-32	48,093,102	11·81	5,114	5,704	3,488	14,306
1930-31	34,871,526	8·34	7,052	5,253	1,733	14,038
1929-30	23,345,093	6·40	7,833	3,675	1,688	13,196

Average Area of Wheat Crops per Holding.—Central, 142 ; Lower North, 272 ; Upper North, 274 ; South-Eastern, 105 ; Western, 423 ; and Murray Mallee, 372 acres. Total State, 275 acres. There were 1,713 farms with less than 50 acres for wheat, and of these 771 were less than 20 acres.

Productivity of Wheat Areas—South Australia.

Comparative analysis of the Productivity of Wheat Areas per acre for the seasons 1931-32, 1932-33, and 1933-34. Total average inches rainfall in agricultural areas (with April-November totals in parentheses)—1931, 15·11 (13·27) ; 1932, 18·16 (14·70) ; 1933, 13·73 (11·66).

Production Groups.	No. of Wheat Growers.			Area of Crop.			Production.		
	1931-32	1932-33	1933-34	1931-32.	1932-33.	1933-34.	1931-32.	1932-33.	1933-34

PAPERS READ AT CONFERENCES.

EYRE'S PENINSULA (WEST), CEDUNA, JULY 4th, 1934.

THE VEGETABLE GARDEN.

[By T. R. ZIPPELL, Mudamuckla.]

In preparing a garden, I prefer a piece of scrub land, as it does not require so much manure, and grows a better crop the first season. All stumps, sticks and rubbish should be burnt on the ground, and the ashes dug in. The ground should be dug with a spade 1ft. deep, and at least 1 month before the ground is wanted for planting. By leaving the ground for several weeks after digging, the air and sun sweeten the soil, and better growth is the result. A good coating of stable manure and a sprinkling of super should then be given and dug in. When levelling the surface with a rake, bank up the sides of the bed with the top of the rake, so that the plants can be given plenty of water when they are big enough.

Sow the seeds in the open; the seedlings get hardened and do not get such a check when planted out as when grown in a sheltered place. I often sow them at the end of the bed that is to be planted. In this district lettuce, cabbage, and cauliflower seeds should be sown about the end of February, when one has the water to keep them going. I have often had lettuces ready to cut by the time the first rains come, as they grow very quickly while the ground is warm. Where water has to be considered the seeds can be planted in March, and set out after the first rains. I prefer planting out turnips in the paddock on a piece of scrub land. Mix the seeds with super, and sow through the super box of the drill. Lettuces should be planted out 1ft. apart in beds wide enough for three plants. Cabbages and cauliflowers require more room, and should be planted 18in. apart. Silver beet is a good standby; it grows all the year round, and does not require very much water. Rhubarb is another good plant to grow, and once planted does not require much attention, provided it gets plenty of water. A little stable manure and super hoed into the top of beds between the plants will keep it growing. Before planting, the ground should be trenched, and plenty of stable manure put in. The first year very few stalks should be pulled to enable the plants to get well rooted. A dozen plants should keep a family going once the plants are well rooted. Apply super to the plants on an average of once a week. It should be hoed in, and the bed watered well. The hoe should be kept in use for loosening the soil and keeping the weeds in check.

Tomato seeds should be sown in July, and provided they are protected from frosts, should be ready to plant out in early September. Trench the ground, and dig out the trenches a fortnight before planting. They can then be filled in with manure with some of the surface dirt mixed in with it. Add some super as well, as it helps the plants once they start to grow. If lime is scattered around the plants when they start to flower green grubs will not attack the tomatoes when they set on the bushes.

August is the best month to sow summer vegetables. Cucumbers grow best in trenches prepared the same as for tomatoes, and along a fence; they do better if they have something to creep on. Nip off the ends of runners when they start to flower, so that the plants will set fruit quicker. Super or liquid manure should be given once a week, and bigger crops will be grown by their use. Where water has to be considered in growing cucumbers, the best method is to dig out a hole 3ft. in diameter, manured, and a kerosene tin put in the centre, with half the tin showing out of the ground. Holes should be punched in the bottom of the tin for the water to soak through into the ground. One plant

can be grown on each side of the tin. I usually put in twice as many seeds as I want plants, as all the seeds do not usually germinate, and plants can be pulled out if there are too many, or transplanted. Cucumbers and melons transplant easily if given a little attention. The apple cucumber is the best variety; it grows a big crop, and is the sweetest for eating. The long cucumbers have a tendency to go bitter. Floraphos is a good manure to use.

New Guinea butter beans are also easy to grow, provided they get plenty of water when they set fruit. I trench the ground the same as for tomatoes, and have a trellis for them to creep on.

Melons are easy to grow if given plenty of stable manure and kept watered. The Ice Cream is the variety of water melon I consider the best; the flesh keeps firm and cool, even in hot weather.

I always consider the main point in a garden is to have the ground rough dug some time before it is wanted, and when the plants are growing keep the ground well hoed and free from weeds. The application of super is also a big help; it strengthens the plants and makes them grow quicker.

SHEEP ON THE FARM.

[By A. R. MAGUIRE, Mudamuckla.]

Once a farmer has sufficient land cleared and provision made for water, he should lose no time in securing some good breeding ewes to start his flock. Buy them in the wool for preference, so that the quality and staple of wool can be judged.

If not already in lamb, choose a good Merino ram, and mate the ewes in December so that the ewes will begin lambing in May, by which time (in normal years) there should be green picking for them.

It is advisable to reserve a paddock as near the homestead as possible for the lambing ewes, so that a watch can be kept early and late. Thus a young ewe which may be having difficulty in lambing can be assisted, and it will also tend to check the ravages of the fox.

Treat lambing ewes—and, in fact, all sheep—as quietly as possible, and better results will be obtained. Confidence in the flock master will make them more contented. Do not use a sheep dog unless absolutely forced to do so.

Breeding ewes should be in good condition, but *not over-fat,* and it will be found beneficial to give them a few sheaves of hay morning and evening, scattering it about the paddock. This makes the ewe take exercise to get her food, and being so often among your sheep tends to give them confidence in you, which is one of the secrets of successful handling of sheep on the farm. If unable to keep the lambing ewes separate from the rest of the flock whilst lambing through lack of paddocks, separate them at the earliest opportunity, and tail lambs 3 to 4 weeks after dropping. See that the sheep always have plenty of water, where they can get to it whenever they wish. Provide them with either salt licks or coarse rock salt. Finely ground rock phosphate and sweet ground bone meal will be found to be of benefit, and some of these should be placed where the sheep can take what they require.

I favor the Merino for these districts. They are hardiest of all breeds, and are not so bad on the fences as some other breeds. Some people favor Corriedales, others Dorsets, Shropshires, Southdowns, and Leicesters; but for all-round Eyre's Peninsula conditions I do not think any other breed will ever replace the Merino from its position as general favorite. Do not adopt the practice of turning all the sheep on to the fallow. Keep a few sheep specially for that purpose; 15 to 20

sheep will keep a fairly large piece of fallow land very clean, provided, of course, that it is worthy of the name of fallow in the first place. By doing this there will not be so many sheep with badly sanded backs at shearing time.

Wherever possible, sheep should be dipped within 1 month of shearing; it is beneficial to the sheep and the wool, and therefore, of course, to the farmer. Crutch at least once each year to check the ravages of blowfly, and it also pays to clear any wool away from the eyes at the same time, if the sheep are heavily woolled. Do not make the mistake of having a few sheep in each pasture paddock. Give them one paddock at a time, and change them to another at intervals. Change is an important factor in sheep management.

Cull carefully; remember "only the best is good enough." It costs no more to feed a well-bred animal than a mongrel, and is much more satisfactory. In breeding for mutton for home and local consumption, either the Shropshire or Dorset Horn will be found to be a good ram to mate with either Merino or Merino-Lincoln on Comeback ewes. They impart size and quick fattening qualities to their stock, coupled with a good saleable class of wool, and are generally more prolific breeders than the pure Merino. It is true we have no satisfactory market for fat lambs on Upper Eyre's Peninsula at present, but present conditions will not always prevail.

The day is coming, in spite of pessimists, when with the extension of the Tod water mains (wherever possible), and with better water storage facilities on other farms, almost every farm will have its flock of sheep, according to its carrying capacity. Then there will always be someone wanting to buy and someone wanting to sell, and thus a market will be created for any surplus. Rail freights are against us in the matter of transport of fat lambs to the Port Lincoln Freezers, and the long, slow journey is another factor against such a scheme; but private enterprise has seen fit to provide a butter factory, which if loyally supported, may provide us with a freezing plant capable of dealing with surplus lambs for many years to come.

In conclusion, choose good class sheep of whatever breed you prefer, put them in good paddocks, surrounded by good fences; drill in oats on as much of your stubble land as you can spare; save all your cocky chaff each year, and also make a stack of straw after each harvest. Hand feed in the late summer and early winter, or until the grass has strength in it. Give them the necessary water and quiet, careful attention. Look on them as an asset, not just merely a sideline. Remember also that "half the breed is in the feed."

THE WORKING OF A FARM—1st JULY TO 30th JUNE.

[By A. C. Watson, Mudamuckla.]

Seeding completed, the first jobs should be the killing of rabbits, and fencing. Such work as new buildings, scrub clearing, and shoot cutting should be considered before fallowing, which should be started about the first week in August with a mouldboard plough. Precaution should be taken to try and prevent drift and take-all; therefore I would prefer to fallow only where the grass has been burnt or well cleared up by sheep. Do not plough in more grass and rubbish than is necessary. The old theory of turning coarse grass and straw in to keep the land in good heart is long passed; it only keeps the soil open, which induces take-all. Plough 1in. to 2in., and keep at least 2 chains from fences on the north and east sides, as most of our lifting winds come from the south-west.

Fallowing should be completed by the middle of September, and in the light soils, such as we have generally, sheep should be the only "implement" required until seeding time.

[*Papers Read at Conferences.*]

Shearing comes after fallowing. Shearing being completed, there should be a few idle weeks in which a farmer may have a few weeks' holiday, if finance permits; or such jobs as oiling harness and repairs to machinery can be attended to. An early variety of oats can be grown for hay so that, if possible, the hay can be cut and carted and stacked before the commencement of reaping.

For a harvesting plant I prefer strippers and power winnower, although a harvester would be a suitable machine to work in conjunction with strippers on farms where over 600 acres are to be harvested. All effort possible should be made to have the harvest completed by the second week in January, to give plenty of time to get ready for burning. Here we have to give a little thought to the future at this time of the year, as it may mean the difference between success and failure. First of all, a farmer should consider his financial position, and take a view of what money he can safely spare for the coming year's expenses. Is the farm paying its way? If not, I think it would be wise to endeavour to make it so by increasing or decreasing the area sown with wheat. Consider the meat and wool side of the problem, and dairying, for cutting out unnecessary wages for labour.

It is impossible to burn scrub on suitable days without the fire becoming a bad master unless there is a break of at least 5 to 10 chains on the front side. Therefore, I recommend to clear scrub where the fire will blow on to a stretch of unburnable country. New land should be ploughed as soon as possible after burning, because the sun and light rains which we are likely to have at this time of the year will help the fertility of the land.

If the soil is dry enough, commence sowing oats the second or third week in March, and follow on with new land, or clean stubbles. If the season opens in the latter part of April, be prepared to start on the fallow with a combine as soon as weeds appear, and put the land in before the soil gets too cold.

Seed and super should be sown at the rate of 50lbs. to 55lbs. per acre. I do not think it a good practice to sow wheat after the first week in June, and then finish up with an early variety. Finally, I recommend Late Gluyas and Ford for mid season, and Early Gluyas for a later sowing.

WHEATS BEST SUITED FOR THE DISTRICT.

[By C. Bergman, O'Loughlin.]

Considering the nature of the land in this district, which ranges from rather poor shallow soil to deep rich red loam, one must bear in mind the great difference between these soils. The average rainfall per year is about 13in., useful rain of about 8in., and very often less, with a dry spring. It will be seen that late wheats cannot be grown successfully under these conditions; therefore it is necessary to concentrate on mid-season and early varieties, with a preference for the latter. But it is wise to have some mid-season varieties to put in early, for it is advisable to get an early start on seeding. A dry spell is often experienced during the growing period, and if all early varieties are sown they will very likely run to head too early, and be caught by frost; hence the reason for some mid-season varieties. Wheats that were grown 15 or 16 years ago have gone right out of favour, not through climatic conditions, but mostly owing to changes in soil conditions. A few of the varieties which were very popular in those times are as follows:—Marshall's No. 3, Boomerang, Rattling Jack, Federation, Gluyas, Walter's, Marshal's Prolific, and Club Head. All these wheats, with the exception of Gluyas, have been discarded, and all are inclined to be late varieties.

When these varieties were grown with success, the soil was practically nearly all virgin ground, free from weeds, and the practice then was to sow as early as the end of February and beginning of March to catch the early rains, and by using these late varieties there was less danger of the wheat running to head prematurely. But since then things have altered considerably, owing to the prevalence of weeds and grasses, which have made the soil too dirty for early working. Farmers have been forced to alter the methods of 15 years ago by having to wait for rain to put in the bulk of the crops, which has lessened the growing period and made the use of quick growing early varieties imperative.

The most suitable and popular wheats for the district are Ford, Smut Proof, Quality, Nabawa, Joffre, Early Gluyas, Aussie, Canberra, Gluford, Gallipoli, Waratah, Late Gluyas, Sultan, and Felix. In considering these varieties—taking their good and bad points—Ford seems to hold the premier position, with other varieties running very closely. Ford is an ideal wheat; it is not so subject to red rust, and should be used more on the rich red loam soils which are likely to produce a rank growth, for these soils are more likely to encourage rust than the poorer low ground. One point a little against it is that it grows rather tall. Smut Proof is also very suitable, inasmuch as one never finds any smut in it, and it is not necessary to pickle it, which is a considerable saving. This variety should never be sown dry, the best time to sow being after the first rain. It will then stool and produce a heavy crop. It is also a very good wheat to handle. It reaps very easily, and a good sample is obtained. It is quite free from white heads, and it weighs better than any other wheat. It has a fairly high percentage of gluten, which is so necessary to keep up the standard of local wheats. Quality is very similar to Smut Proof. Nabawa is on a par with Ford, but inclined to stand up in the early growing period. Canberra is a very good wheat, but very susceptible to ball smut. It needs careful pickling, is quite a good wheat, and yields fairly heavily. Early Gluyas is a very good wheat which has stood the test of time, and is still amongst the best varieties, although it has the fault of lodging badly. It makes up for this in other directions, one of them being that it is a good yielder of even and good coloured grain. Every farmer should sow some of this variety, but do not sow too much, and reap it as soon as it is ripe. Aussie is quick growing, much quicker than Ford. It covers the ground very quickly, which enables it to choke out rubbish. It is a good yielder, but it goes down rather badly. It also has a good plump grain. Gallipoli is a heavy yielder, but is a very poor milling wheat with a low gluten content, which is detrimental to the export trade. Late Gluyas has somewhat deteriorated because of the difficulty in being able to grow a good plump grain during recent years. It is very subject to rust, and also ball smut and black rust. A number of farmers have therefore discarded this variety.

Farmers should do a little experimenting with new varieties to try them out, but not sow large quantities until they are certain that they are suitable for local conditions.

WHEAT GROWING IN COUNTY WAY.

[By J. W. BLUMSON, Laura Bay.]

The suggestion which is constantly being made to abandon wheat areas of low production has led me to review the position in County Way, where I have lived for 28 years.

County Way is about 500 miles from Adelaide, and is adjacent to Thevenard, a deep sea port, and terminus of the Port Lincoln railway (completed in 1915) and the Penong railway lines. The fishing industry employs about 100

men in the district, and a gypsum factory, now idle, is situated at Thevenard. The Mission Station, Koonibba, is in the County, and there are about 60 native children taught there.

Historical.—The first record of white men visiting South Australia was in the year 1627, when Captain Nuyts was in this district with his ship *The Golden Sea Horse.* The name "Nuyts Archipelago" was given to the islands adjacent to this district. Captain Flinders in the sloop *Investigator* was here in 1802. In November, 1840, the explorer Edward J. Eyre passed through the district on his famous overland trip to Albany. The first settlement here was a whaling station at Point Brown. In July, 1877, the telegraph line Port Augusta to Eucla, which runs through the district, was completed, a distance of 759 miles. In the late fifties most of the district was allotted as pastoral leases, and many wall shafts, house and fence ruins are relics of station enterprise. County Way was proclaimed in 1889, with an acreage of 1,670,000 (886,160 surveyed), 990,000 acres being unoccupied in 1927. The Murat Bay District Council was formed in March, 1925, and with the County of Way includes the Hundreds of Hague, Carawa, Petina, Nunyah, and Pureba. The Murat Bay Vermin District and parts of the Petina and Penong Vermin Districts are in the County of Way. On March 25th, 1882, Captain Gulloch bought the schooner *Woolomia* for the Streaky Bay and West Coast trade. The greater part of the County was covered with heavy mallee and titree scrub, and most of the scrub has been cut with an axe, at a cost averaging about 6s. an acre in 1907, 10s. in 1913, and £1 in 1927.

The rainfall is better in the southern part of the district, and averages about 12in. per annum, and the useful rain falling between April 1st and November 1st is about 9in. average for the County. Soil analysis and the use of abundance of water have shown that our soil is rich in plant food. Smoky Bay soil contains as much as 45 per cent. of lime. I believe the late Mr. W. McKenzie, was the first settler to grow wheat, in the late eighties, at Denial Bay.

The first official statistics are for the year 1890-91, when 808 acres of wheat yielded an average of 8.05 bushels per acre for the County of Way. During the following years many farmers, mostly from Yorke Peninsula, took up land, and production increased. In 1912-13 434 men were employed, and cropped 102,688 acres of the 681,856 acres leased, of which 215,403 acres were classed as cleared. Although land that has been "mullenised" and burnt is classed as cleared it cannot reasonably be compared with land without stumps.

One of the trials here is that this land will not stay cleared for cultivation; that owing to the action of the wind, the trampling of stock, and the firming of the ground dead stumps rise out of the ground and have to be dealt with repeatedly before the land is fit to cultivate. Some of the stumps are too big to plough out, and would not rot in 50 years, and until they are got rid of they cause considerable depreciation and loss and much labour.

Early settlers had to undergo hardships. They had to cart water and feed long distances, and sometimes condense salt water for stock. There were no jetties to land goods, and drays had to be driven into the sea to ship the wheat into cargo boats, and to load goods for the settler. Murat Bay jetty was built first, and in 1910-11 jetties at Smoky Bay and Denial Bay were built, and also a landing at Laura Bay. Thevenard jetty was built about 1916, at a cost of £168,528.

Water Supplies.

Excepting the soaks at Point Brown and Denial Bay, there were practically no supplies of underground water fit for stock, and consequently settlers had to build underground tanks to conserve water from surface catchments. The Government also built in 1925, tanks holding 6,888,000galls. According to the Murat Bay Council assessment of 1925, the settlers had built tanks of cement

concrete, &c., to hold 20,211,000galls., an average of 62,500 per assessment. Settlers had also spent considerable time and money sinking wells in the search for water. In spite of the provision made, many settlers have had to spend considerable time carting water.

During the past six years there have been few showers heavy enough to run water off the ground, and but little water has been caught. In July, 1928, the Tod River water scheme was completed as far as Thevenard, and has been the means of keeping many supplied with water when otherwise it would have been unobtainable. Many farmers are outside the reticulated areas, and have had a very unprofitable time water carting. When I came to the district 28 years ago a pioneer of 17 years residence told me that he had never had a failure, but every year some dry period, pest, disease or storm had reduced the yields that promised. My experience has been similar, excepting perhaps in 1916-17, when the County produced 1,399,073bush., average 14.30bush. per acre (Eyre's Peninsula was 12.90 bush. per acre), but we have not been fully paid for that wheat yet, and much of it was destroyed by mice and mismanagement.

The Railways made available only a few new holdings, but it was a benefit to many who had to cart long distances. On the other hand, some of us have to cart long distances, because our port has been closed by the railway. Wheat was loaded into overseas boats before the deep sea port was suggested, and it now costs more to send wheat from Smoky and Laura Bays to Thevenard than it used to cost to send it to Port Adelaide. Our boat service with Port Adelaide is now confined to one company, whereas in 1912 there were three companies running steamers, and freights were about half present charges.

Only a few settlers are able to receive the full benefit of the Tod River water; it is too costly to reticulate the water to our farms. Many of us have spent hundreds of pounds in catchments and tanks too good to abandon, and they have to be kept in repair. Many have not sufficient land cleared to enable them to keep enough stock to make the water supply profitable, and land clearing is very expensive. Land in this district has rarely been sold for more than a fraction of the cost of the improvements thereon. The farmers in this district have generally spent all available money on improvements, but the sale value is not an encouragement to do so. I think investigation will show that in 1913 South Australia was prospering as the result of good seasons and fair prices, and if the whole history of the State is considered, and we take the year 1912-1913 for comparison of wages, salaries, prices, &c., we err on the side of generosity. In 1912-13 there were 434 men engaged in farming here; in 1931-32, 382, a decrease of 52 men, when there were 23 tractors used. In 1912-13 they cropped 236.6 acres per man; in 1931-32 307.6 acres per man, an increase of 71 acres per man. In 1912-13 there were 2,927 horses (per man, 6.74); in 1931-32, 2,180 horses (5.70 per man). In 1912-13, 458 head of cattle, and in 1931-32 1,178 head of cattle. In 1912-13, 18,915 sheep; in 1931-32, 31,115 sheep. In 1931-32 there were 9½ acres of cleared land per sheep, and the wool clip in 1932 averaged 8.32lbs. Land cleared in 1913 was 215,403 acres, and in 1932-33 295,247 acres. Land leased in 1913 was 618,856 acres, and in 1932-33 516,867 acres. The average wheat yield for the County for 38 seasons 1890-91/1932-33 was 5.08bush. per acre. In 1912-13 an average of 30.7lbs. of artificial manure was used per acre, and in 1932-33 only 23.5lbs. per acre. In 1893-94, 1894-5, and 1895-6 statistics were not collected. The average seems low, but we find that the State yield for the 7 years 1896-97 to 1902-3 averaged a little less than 4bush. For the same period Mr. Joel Lowe, of this district, averaged slightly more than 9bush. All experts agree that we cannot grow wheat under present conditions profitably. It is true that on an average we produce enough wheat per man employed to feed more than 250 persons,

truly a performance to be proud of, but at the end of our year's work our balance-sheet shows that we have no personal gain in most cases, but depreciation and loss.

Until 1913 the County was making progress, and the State prospered. Wheat prices had averaged about 3s. 9d. per bushel since 1900, and we could meet our expenses. The settler who goes furthest from civilisation to develope land pays most for all his requirements and receives least for what he has to sell, and because of taxation being passed on he pays more than his share of taxation. I have spent a considerable time among old invoices, price-lists, and other accounts, and I declare that the expenses of wheat growing and living in this district are double what they were in 1913, and wheat is now 2s. 5d. and lower. The cause is due to the tariff, taxation, increased freight charges, and other similar charges. Merchants, manufacturers, and importers transfer the expense of taxes and Customs duties, other expenses, and bad debts, &c., to the price of his goods, and the purchaser pays. As a result, we find that, in spite of improved methods of manufacture, improved methods of transport, and low prices of metals and other commodities, we are asked twice as much for goods we require as we paid in 1913. Although some goods seem to be as cheap in price as in 1913, the quality is much inferior. I bought rabbit traps this year, paid nearly three times the 1913 price, and in more than half of them the spring has broken. We cannot pass our expenses on, and our efforts to pay expenses by increased production have only made matters worse.

Assistance to Farmers.

Much has been said about the assistance given to farmers, but if tariff charges and taxation are investigated it is found that such imposts have increased since the price of wheat was profitable. Our assessment value for land tax was increased at the end of 3 years' ruinous drought and crop failures. Our rents, rates and taxes are generally due in advance, and fines and interest are imposed for late payment. If a farmer tries to pay his way he is treated harshly if accounts are a few days late.

The replacement of plant and machinery under present conditions is a problem, and the abandonment of adjacent farms makes it difficult for survivors to cope with vermin. The settlement of abandoned farms in this district should be expedited. They depreciate in value, and should be treated like perishable goods, sold to the highest eligible bidder. If it were not for the artificial conditions created by tariffs, taxes, bounties, we would have been able to manage, in spite of the low price of wheat. Our hope of survival is to reduce costs of production, and to keep our expenditure as low as possible. We should be able to increase our average yield by better methods. Only about 8 per cent. of our acreage is on fallow at present; but we must balance the ledger to be on a sound basis.

I believe more time and money has been spent on rabbit destruction in this district this year than ever before, and, in spite of this, a lot of wheat has been destroyed, and rabbits are still a nuisance. Yet no effort is being made to settle idle blocks. On an average there were 71 acres more per man cropped in 1931-32 than the average of 1913, but the increased production does not pay owing to the increased cost of the larger machinery used, trucks, tractors, and other production costs.

Farming in this district is the extreme contrast to the unskilled worker unemployed in the city. While the unemployed man looks for years sometimes without finding work, a settler here can put in his double shifts of 8 hours before dinner and 8 hours after for a lifetime without having the satisfaction of having caught up with his work of land clearing and improvements. At the end of his career there will be a farm capable of feeding hundreds, but he will most likely have nothing else to show for his industry and self denial. When we have

good harvests and prices the extra proceeds have been spent on improving our bit of Australia, but now we cannot even keep our bit in order under present conditions.

The County of Way and adjacent counties were settled before the Advances to Settlers Act was passed, and the talk of abandoning these areas hardly merits discussion. One has only to contemplate the cost of the improvements made by settlers for which compensation amounting to millions of pounds would have to be paid to perceive the madness of the idea. These settlers have paid rent and taxes in advance from the time they applied for their holdings, and they are now carrying a heavy load of which taxation forms the bulk. They deserve special treatment because of the conditions of their life, work, and expenses, and in the past when drought prevented them from paying rents and taxes they were charged fines and interest, and their load increased. It would be more reasonable to remit Government charges when the rainfall was below, say, 9in., and it would also be just to remit motor taxation. I would like to stress the point that we have paid our rent and taxes, but have been unable to make provision for the renewal and proper repair of our plant and machinery, and we must soon acknowledge that the latter is most important.

BOOKKEEPING ON THE FARM.

[By C. HALAHAN, Ceduna, July 4th.]

I have attempted to give you a system whereby a record can be kept in the simplest way, involving a minimum of writing and records.

We all realise that any system of bookkeeping is distasteful to practically all farmers—and not only to farmers, for I have seen few people who take kindly to bookkeeping.

The system is really that of a diary, and the only book to be kept is that diary. These special books can be procured at a reasonable cost, one that will suit the requirements of most farmers costing only 3s. or 4s. ("Invicta" Australian Diary, No. 5).

The book is headed for each day in the year, three days to a page, or a week to a double page, with a money column at the side. As well as this there are pages at the back double ruled as a "Cash Account," a page for each month.

To start with, and there must always be a beginning, my suggestion is that the farmer make his financial year the same as is required for income tax purposes. It is a good thing to have uniformity, and June 30th is really a good period for a farmer to finish his year, as at that time, under reasonable conditions, he will have sold his wheat and wool, and also completed his seeding, and that period is, if any is, a slacker one for him.

The beginning will involve the compilation of a balance-sheet. This really is not difficult, but it must be honest. It is no good for a farmer to try and cheat himself, and the figures in that balance-sheet must be those of the true value of his assets and his total liabilities.

ASSETS.

I will take the *Assets* first, they are much the most pleasant to deal with.

The first of these is, of course, the farm as it stands, including improvements. This should be put down at the value that the farmer considers it is worth to him, and in later years the value can be increased or decreased, though it is wisest to settle a value which is only increased by permanent improvements, or decreased by any drastic change in the value of land in the district.

Next is the plant. Make a list of all implements separately, putting a value to each. For that value I would suggest the original price, less depreciation to date. Thus if a stripper cost £150, and the life of it will be 15 years, its annual depreciation is £10. If it has been in use five years it has depreciated £50, and its present value is £100. In this way the value of the plant can be ascertained, and the annual depreciation worked out, too. For later years the only figure to take is last year's value, plus the purchase price of any machine purchased during the year, less the amount of depreciation last year, and one year's depreciation on the new machine, if any, taken into account.

Then come the horses, and these should be valued in the same way. If Duke is 6 years and worth £28, it means that his annual depreciation is £2, as he has, say, 14 years more service. These figures are not supposed to be correct, but are used only as illustrations. In the valuing of horses though, their worth to the farmer, or the sum he could replace them for, is what should be taken into account. If Blossom is 15 years, she has only five years' work ahead, and £20 is a big value for her, compared with Duke at £28, despite how good a mare she is.

All other assets—sheep, wheat on hand, other grain, hay, motor car, cash in bank, moneys owing to the farmer, suburban blocks or township properties should be listed and valued, and that completes the assets.

Liabilities.

The first is the capital debt on the farm, if any, whether to the Advances to Settlers Department or to a private mortgagee. The total owed, capital, arrears of interest, and current interest should be shown.

Next are amounts due to the Government or local bodies. Land tax, rents, water rates, district council rates, fencing loans, &c. The total owed in each case must be shown, not only the current year's dues. Then comes amounts owing on machinery, or for 'super and bags, to be followed by the storekeepers or other local tradesmen, and any other debts that the farmer may have.

After a full list of assets and liabilities has been made, by taking the liabilities from the assets a surplus or true worth may be arrived at.

So much for the beginning, which you may say is a long one, but it is necessary for each farmer to have this record, and I would also suggest that he record a list of any property that may be on the farm, but which belongs to any other member of his family, showing to whom those things belong. This is a definite record, and a wise one to have.

It will be necessary to compile this balance-sheet at the end of each year, and a wise practice to keep a copy of it in the diary, say, on the page allotted for the last week in June, and the current entries for that period could be included with those of the previous week.

Keeping of Current Records.

I would suggest that if the diary is not written up each night it be written up once a week, as the dealings of the week can always be remembered at the end of it.

Any transaction of a day should be recorded on that day, such as "Sold to A. Butcher 20 sheep at £1." If these are paid for the amount can be entered immediately in the cash column for the month under the correct date. All sums received should be entered on these cash sheets, so that a complete record is kept of all money handled, including that for wheat and wool. The word "Paid" could also be entered against the diary note, and this shows that the transaction is closed. If only a portion is paid a note of this could be made, and so a record kept of the amount still owing.

A note of special purchases could also be kept, such as "Bought of B. Book one horse, 'Tiger,' £30 cash," or "Received 15 tons of super from Superphosphate Co.," or "Received 1 ton of iron from Builders Ltd."

For expenditure, of course, I presume that each farmer has a trading bank account, and most payments will be made by cheque. A complete record should be kept in the cheque heel thus:—Paid J. Smith £20, 1 horse, "Lofty," or paid Superphosphate Co. £30, 6 tons super, or change £10, being garage £6, parts £2, change £2. The amount of each of these cheques can be written in the cash sheet where a record should also be made of any cash expenditure from moneys received in cash and not banked, or the moneys obtained from cheques cashed.

In this way a record of the receipts and expenditure can be kept quite easily and efficiently, and also a record kept of any amounts owing to the farmer. The diary will also be found useful to keep all sorts of records, which will not only be interest, but should prove valuable for future reference.

While mentioning records I would like to say a word on statistics. In my opinion the collection of these is a vital matter to the State, and the figures they show invaluable to anyone who is making inquiries about the district.

We all know that many men do not give their correct figures, and in this way they harm not only their district but themselves. An illustration of this matter was shown here recently when the question of a butter factory was under consideration. Then it was found how very far short of the true figures were those that could be obtained from the Statistical Department with regard to the number of cows in the district.

I think that all farmers would do not only themselves, but also their district, a great service by being more careful in the statistical figures they supply.

My idea is that each farmer should keep records, not necessarily on the lines set out by me, but in some way that will give a fairly accurate statement of his affairs at any time, and one that can be followed by any person who may have a attempt to do so. The system I have shown is only a suggestion, but it appears to me to be a simple one which would not involve much labour, and would be easy to follow.

BALANCE-SHEET, JUNE 30TH.

Liabilities.	£
Advances to settlers	300

CONFERENCE OF UPPER NORTH BRANCHES, WILMINGTON, JULY 18, 1934.

THE ABERDEEN-ANGUS CATTLE.—BREEDING FOR CHILLED EXPORT BEEF.

[By C. COLE, Wilmington.]

Although not so well known in South Australia as in the Eastern States, the Aberdeen-Angus breed has become more prominent of recent years.

This breed is now becoming very popular in New South Wales and Queensland, and of recent years importations of very valuable stud animals have been made from Scotland to the herds of the leading studs, to improve the breed to the highest standard possible.

Documentary evidence shows that in Aberdeenshire in 1523, and in the old territory of Angus—now forming part of Forfarshire—as early as 1863, Aberdeen-Angus formed part of the general farm stocks passing under such names as Angus Doddies and Buchan Humlies. Up until well into the 18th century the main purposes of cattle were for tilling the soil, but with the great increase in industrial population which marked a somewhat later period came a corresponding demand for meat.

Then came the evolution of the Aberdeen-Angus breed, the first and most prominent name in the list of improvers being that of Hugh Watson, "Keillor," of Forfarshire, the outstanding pioneer. William McCombie has been called the master builder, and Sir George Macpherson Grant the man who placed the coping on the Aberdeen-Angus structure.

In 1808, Hugh Watson received from his father 6 of his best and blackest cows, together with a bull, as a nucleus of an Angus Doddie herd. He then visited the Trinity Muir Market, Brechin, and secured the 10 best heifers and the best bull he could procure, showing the greatest characteristics of the breed. After the herd was in existence for over half a century, it was dispersed in 1860.

Hugh Watson's motto in his system of breeding was, "Put the best to the best, regardless of affinity or blood." Breeding in and in must be done judiciously and cautiously, for while it is the readiest path to uniformity and perfection in the hands of a thoroughly competent breeder, it is the surest and swiftest to bring destruction to the animals and interests of the incompetent breeder. To-day there is no herd in the world that is not indebted to Keillor blood, and not a few of the most noteworthy pedigrees trace back to animals bred by Hugh Watson.

Aberdeen-Angus Cow.

William McCombie, of the famed Tilly Four Herd, was formed in 1832, and dispersed in 1880. Then Sir George Macpherson Grant's Ballindalloch Herd came into prominence. This herd is still in existence, and is one of the leading herds in Scotland at the present day, but will unfortunately be dispersed in August this year.

The breed was introduced to New Zealand before Australia, the first importation into Australia being made in 1870.

The three principal beef breeds in Australia are the Aberdeen-Angus, the Shorthorn, and the Hereford. All three have good points, but each breed must be treated on its actual merits as a producer of beef that completely satisfies the demands of the London market. That the Aberdeen-Angus and its crosses satisfies this demand more fully than any other breed, there is not the shadow of doubt, and their numerous successes at fat stock shows, on the hoof, and in the carcass in Britain and other parts of the world testifies to their superior quality. Indeed, the first-class retail butcher prefers the Angus and its crosses to any other beef breed.

[*Papers Read at Conferences.*]

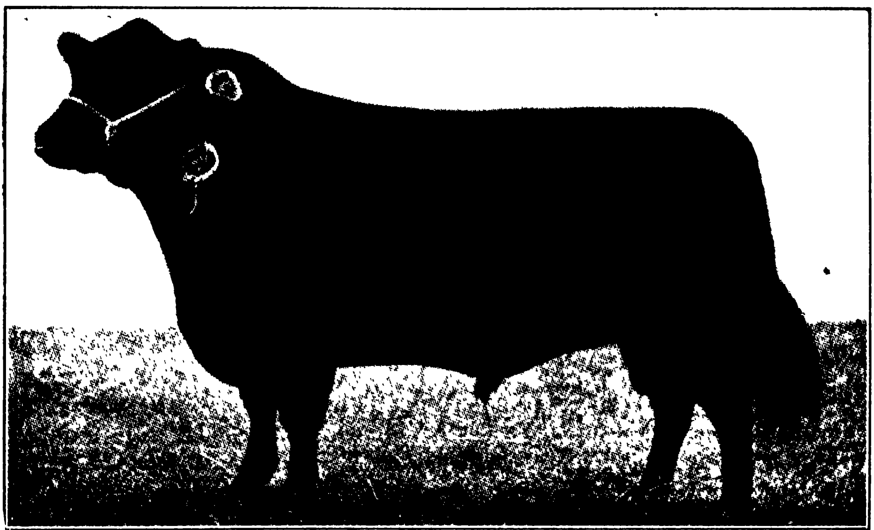
CHANGES IN EXPORT TRADE.

The Argentine had reached its peak of "cheap" production, and was encountering difficulties in meeting the ever-increasing cost of beef production.

The public's taste was changing in England, and the sale of frozen beef was becoming a difficult problem. Experiments at the time were being carried out with the "chilling" of beef for export, as it was realised that "chilled" beef would rapidly oust frozen beef from the market. The mode of living throughout the world had changed subsequent to the war. Residential flats, equipped with modern household appliances, such as freezing machines and electric cookers, were in demand. The desire for outdoor sport and enjoyment resulted in the production of the "baby car," so that home life became drastically changed.

SMALL JOINTS NOW REQUIRED.

This change in home life had a marked effect on the cattle industry. The housewife demanded a small, compact joint, to fit in the electric stove or home freezer; she wanted a lot in a little space—a short, thick roast, with little waste and small



A Typical Two-year-old Bull.

bone. The cheap or small car meant that the joint purchased was required for perhaps only one meal, as the remainder of the Sunday or holiday was spent in the country or at the seaside.

Again, in America especially, it was found that the railroad companies were keen purchasers of high quality beef, whilst in New York the demand for improved quality of beef was ever on the increase.

In Australia, however, there was no such demand, and even to-day it is found most difficult to purchase at all times a uniform quality of "modern" beef.

To be successful in any project, it is essential to have an objective in view—a standard of perfection, perhaps difficult of attainment, yet worth the trouble when the goal has been achieved. In our case the objective is the successful breeding of a steer which will be acceptable to the most discriminating buyers.

In the past, in Australia, we have grown accustomed to the big 5 to 7-year-old bullock, a beast which suited his time and purpose, and more often than not was capable of travelling long distances to the railhead, and of then being fattened to make up for loss in transit, which in some cases extended over several days.

[*Papers Read at Conferences.*]

Changed Methods Essential.

The change-over to the modern demand will not be brought about as quickly as might be hoped, for not only the breed, but also the breeder's methods, must be improved. One might be safe in saying that the change-over will go so far as to convert present sheep country into cattle country, and *vice versa.* Success in production of the modern steer will necessitate conservation of fodder, pasture improvement, and subdivision of the large runs into smaller paddocks. It may even mean in some instances a change of site for killing works, but in any case an improved means of transport will have to be provided.

However, here in Australia I would advise the average grazier to improve his 2½ to 3-year-old steers. Strive to bring them to perfection, and for the time being let the production of "baby beef" be with the stud breeder.

Watch the breeding of winning steers, and there look for early maturing strains.

Suitability of the Aberdeen-Angus.

In the Aberdeen-Angus its quick feeding and early maturing properties ensure its popularity for the commercial market. These properties find a fitting complement in the favour which is shown to cattle of the Aberdeen-Angus type by the practical men of the meat trade who have to study and cater for the tastes of the consuming public, for it is from the public that there comes the demand for the Aberdeen-Angus, the breed which yields choice quality and those juicy small joints so much in demand under prevailing domestic conditions.

Type of Carcasses for Chilling.

The progressive stages to perfection in the carriage of chilled meat from Australasia as witnessed in recent shipments, leads one to express the opinion that successful experimenting will soon give way to commercial pressure, and the near future see regular shipments of chilled beef from Australia and New Zealand to the United Kingdom.

The several factors leading up to this anticipated successful trade have been contributed by the scientist, the ship builder, and the refrigerating engineer, and it is now up to the breeder to provide the best quality meat for overseas transport in a chilled state.

The mechanical equipment on board ship is made to specification, and the engineer gets the plant that experience has dictated is the most suitable for the carriage of chilled meat. A specific quality of beef cannot be made to order, though breeders by selection of types could help greatly in this respect, and thus the engineer has no choice in the matter of texture in his chilled cargo.

Paradoxical as it may seem, fat in meat is, at the same time, a source of anxiety and a factor of safety to the refrigerating engineer He knows that fat readily absorbs the slightest odour and becomes tainted and, therefore, so far as contamination is concerned, he favours lean meat for transport. Again, he knows that lean meat provides good productive soil for the growth of moulds and bacteria, so he suggests that the lean meat be protected with a covering of fat.

He also knows that a thick covering of fat will act as an insulator and be a deterrent to refrigeration, so he recommends a thin covering of fat in order that the meat may speedily acquire a uniform temperature throughout its bulk.

Still again the engineer knows that the drying of the surface will hinder the growth of mould and bacteria, but as the surface of meat is continually fed with moisture from underlying tissues he calls for protective internal and external strata of thin, fatty tissue to arrest the leakage of moisture to and from the surface of the quarters.

With his practical experience in refrigeration and his studies in biological work, as exemplified in the points raised above, the ship's engineer—who is after all responsible for the safe transport of chilled beef to its destination—is in a

position to develop a specification for what possibly cannot be manufactured either by man or beast, viz., the desirable quarter of beef for chilling purposes in accordance with his views.

The refrigerating engineer's views are that the quarters of beef accepted for shipment should have a thin covering of fat to act as a protective surface against evaporation, mould, and bacterial growth. Further, the meat should be intersected with thin streaks of fatty tissue to arrest the flow of moisture to the surface.

These external and internal layers of fat should not be thick, as whilst they do not arrest evaporation, mould, and bacteria growth any better than the thin layers, they will hinder the refrigeration from speedily obtaining uniform flesh temperatures which is most desirable.

It is generally accepted that small-boned meat is more favoured for chilling purposes because of its lesser susceptibility to bone taint than large-boned meat.

To summarise the qualities of the ideal quarters for overseas transport in a chilled state—the beef should be preferably small boned, and should have sufficient fatty tissue properly distributed—that is, in thin layers—internally and externally to prevent evaporation and growth of micro-organisms, whilst at the same time assisting the maintenance of uniform flesh temperatures.

In the supplying of such carcasses the Aberdeen-Angus should undoubtedly play a great part, for with their minimum of bone, their characteristically "marbled" flesh, and their absence of fatty excesses, and their even cover all over, the Aberdeen-Angus seems to approximate most nearly to the ideal set forth in the professional opinion quoted above. It is, therefore, with the greatest confidence that breeders of the Aberdeen-Angus in Australia can face the future. The Aberdeen-Angus has gone far since its introduction into Australasia. When the *Triumph* sailed from New Zealand in the eighties with the first consignment of frozen meat, a great era was inaugurated; with the perfecting of a chilling process to carry meat from Australasia to Britain a still greater era has been inaugurated, and keeping in view the unrivalled place in beef production which the Aberdeen-Angus has already won throughout the world, we feel confident that with the expansion of this process will go a corresponding expansion of a breed of cattle that is so pre-eminently suitable for Australian conditions, and so firmly established in the forefront of the British meat market requirements.

Type of Animal Required.

The ordinary store cattle utilised on rough country is not the animal that will provide a carcass suitable for chilled beef trade. What is required is a well bred, compact, and well finished beast, the ideal age being from 2½-3 years. Importation of new blood would no doubt improve the quality of our beef. There are, however, good beef stocks in this country, and the essential and most important point is to use care in selecting the breeding stock. But whatever type is selected, the fattening process should begin almost as soon as the calf is born.

Dehorning.

Dehorning of cattle is an essential factor for the chilled beef trade. The bruising caused by horning each other while being driven, in cattle yards, or in the trucks results in a great deal of wastage, whereas the Aberdeen-Angus, being hornless, has a great advantage over other breeds. With the Aberdeen-Angus sire, in addition to transmitting the excellent qualities of the pure animal to its crossbred offspring, 90 per cent. of the calves of the cross will be found to be black and hornless, which is an excellent and profitable method of dehorning animals by Nature.

IMPROVED MEANS OF TRANSIT.

In the Argentine, with the co-operation of the railway companies, trains start and travel and stop without jolting. The cattle are loaded into the ends of the trains which, by letting down the ends of the trucks, are transformed into long corridors through which the animals pass prior to being finally partitioned off into their respective wagons.

ACKNOWLEDGMENT.

I wish to express appreciation of help for writing this paper from the Aberdeen-Angus Cattle Society and the New South Wales *Agricultural Gazette.*

FACTORS INFLUENCING THE FIXING OF PRICES.

[By O. KNAUERHASE, Wepowie.]

The problem of prices is an interesting one, and also very important in economics. An understanding of the principles by which prices become what they are will enable one to see why, for instance, wheat should be cheap and yet bread remain dear. There are various factors having an indirect influence upon prices, but where there is free competition they may all be reduced to the principle of supply and demand. Other factors than supply and demand are usually connected with rings, monopolies, and tariffs.

SUPPLY AND DEMAND.

It is most important that the principle of supply and demand should be grasped. It may be very simply stated thus:—When there is a big supply of a particular class of goods, but a small demand, the prices of those goods tend to go down; when there is a big demand, but a small supply, prices rise. This principle holds good no matter what kind of article is taken into consideration. Suppose a farmer has 10 fat cows to sell, but that the butcher wants only one. Here the supply is comparatively great, the demand small. The farmer may be anxious to sell. It is clear then that under those conditions the price will tend to be low. The butcher has plenty of choice, and the farmer will be willing to reduce his estimates just to get rid of his cattle. But suppose this farmer drives his 10 fat cows to market, and that there are 20 butchers all eager to purchase one. We now have an entirely different set of conditions. There is a big demand, and an inadequate supply. Prices will tend to be high. Now there are some goods the demand for which is fairly consistent, and others where the demand fluctuates considerably. This is true also of goods that are supplied. An example of an article for which the demand is fairly consistent is bread. After all, there is a very definite limit to the amount of bread one man can eat at a sitting, and so the demand for a thing like bread, a staple food and constantly required, is relatively fixed. It might be well to introduce the idea of a marginal price or limit price at this point. A very hungry man might pay 1s. or 1s. 6d. to get a loaf of bread; if he were still hungry he might pay 8d. or so for the second loaf, but he would have to be very hungry indeed before he would be willing to pay more than the ordinary price for the third loaf. In other words, as the need for an article decreases, the less a person is willing to pay in order to get it. The price of the third loaf—the one that a man might still buy, but wihch he does not really need—is called the marginal price, and in general it is found that the price of such things as bread, meat, and so on is the marginal or limit price.

Now take an example of articles for which the demand varies. Such articles are fashion goods. Every woman likes to dress according to the prevailing fashion, and this is a fact well known by the storekeeper. Consequently he asks

a high price for his new season's goods and, of course, gets it. Towards the end of the fashion season the demand has completely fallen off, and prices slump badly.

Goods of which there is a varying supply are chiefly antiques, such as rare pottery, old furniture, and also perishable goods—fruit, fish, &c. When the supply is small almost any price can be asked if there is a demand for the goods. For example, rare skins and furs, for which very high prices are paid. Wool is a good example of a commodity of which the supply is reasonably constant. The price of an article has very little relation to its actual value or worth.

Wheat.

For example, the price of wheat is 2s. a bushel; it may actually be worth a good deal more or a good deal less. The actual worth of an article is not easy to determine.

What are the general factors which determine the price of wheat? Everything depends upon supply and demand. But in the case of wheat the demand is fairly constant; the number of bushels of wheat consumed by the world in one year can be fixed within fairly definite limits.

The only way in which the demand for wheat can be increased is by using wheat for other purposes than bread, or by inducing those who now eat rice and maize to eat wheat instead. Even so, the demand would soon reach a limit. It is clear that there must be a definite limit to the amount of wheat consumed in any one year. Even if everyone ate as much bread as he could, he could not eat more than a certain amount. We must look to the supply, then, for the causes of fluctuation in the wheat price. The production of wheat is by no means steady; it depends upon weather conditions, acreage, disease, etc. It is clear that the amount of wheat produced in the world in any one year may be great or small. In the past there has been a serious over production of wheat; far more has been produced each year than can be consumed. The idea at the back of the Wheat Restriction Scheme was to restrict the amount of wheat produced each year to the same amount or a little more than that which was consumed each year. In that way the supply and demand would be about equal; prices would be fairly steady with no marked fluctuations. Of course, if there were a failure of harvest a very serious shortage would result, with very high prices for wheat as a result. Again, the only effect a war could have would be to disturb the production of wheat and the markets of the world. This might result in a diminished supply, with a consequent rise in prices. A very important point to keep in mind in regard to wheat—and, in fact, all farm products like wheat, wool, and meat— is that they are sold in the open world market. There is competition from all nations; the farmer is not in a position to fix his price, and must take the ruling price of the day. This, of course, is what happens in any market where there is free selling.

Wool and Meat.

In regard to wool the supply of the whole world is fairly constant, and would not vary much from year to year; over a period of years there may be a gradual increase or gradual decrease. It is the demand then that determines the price of wool. Here, of course, a war may play an important part, since wool is required for clothing. But apart from war the demand for woollen goods may vary. If people make large purchases of woollen goods the manufacturer may raise his prices; but he cannot go on doing that, because there comes a point when people will buy cotton goods in preference to woollen goods if the cotton goods are cheaper. Consequently there will be a slump in the woollen industry, with a drop in the price of wool. The present high price of wool is due to several factors.

Either some countries want wool for a special purpose, or the supplies at the woollen mills have run out, or there may be a demand for woollen goods, or the manufacturers may expect an increased demand. In the case of meat there is a local as well as a world market. The local demand is likely to be fairly constant. The overseas trade would vary. The price of beef or mutton, cattle and sheep, would depend on how many head were under offer. The greater the supply of choice beef the cheaper it will be for the producer.

FACTORS INFLUENCING THE PRICES OF GOODS.

Three important items are petrol, machinery, and cornsacks. In regard to these the manufacturer usually estimates the cost of the goods he produces, and then fixes his price to obtain as great a profit as he can. This, of course, may not be very high, particularly where there is competition. In the production of petrol, for example, a number of petrol magnates may form what is known as a ring or monopoly by which they agree not to sell petrol or oil below a certain price. This has been done in America, where the oil wells are controlled by one firm. Where a firm has a monopoly over any goods they may fix the price. In practice the price is usually not too high, as it pays the firm or trust to sell a great deal at a smaller profit rather than little at a high profit. Monopolies have serious disadvantages, but also many advantages.

TARIFFS.

The question of tariffs is really the question of two opposing policies, that of Free Trade and that of Protection. Every country must decide what policy it will adopt, whether it will encourage Free Trade and competition from foreign sources, or whether it will try to protect its local industry and its financial position by means of tariffs. Tariffs are imposed for three main reasons:—(1) To restore an unfavourable trade balance. (2) To protect and build up local secondary industries. (3) Prevent the dumping of foreign goods; and a fourth and important reason is to secure revenue for administrative purposes.

The problem of a trade balance between country and country is one of the most complicated in economics. Fairly simply, it is as follows:—When two countries trade with each other—say, England and Australia—it will not be long before one country will have purchased more than the other. Suppose that Australia exports £100,000 worth of wheat, &c., to England, and imports £150,000 worth of woollen goods. Then the £50,000 extra imports are considered the debt that Australia owes to England, or, as it is usually put, there is an unfavourable trade balance for Australia. It should be noted that it is impossible to pay for goods from another country by money. If, for example, a firm purchases £1,000 worth of clothing from England, the only way in which this debt can be settled between England and Australia is by sending some goods from Australia to England. In actual practice, of course, no goods are sent. Instead, the banks settle this matter. A man making a payment from Australia will go to his banker and send a bank draft. In London an account is kept showing the payments to and from Australia; a favourable or unfavourable trade balance depends whether more goods have been imported or more exported. An unfavourable trade balance is bad for a country, because that country must continually pay more for its imports than is necessary. That is why, for example, the Australian £1 note is worth only about 16s. in England. Tariffs are then imposed to encourage exports and reduce imports as much as possible. This reduces the unfavourable trade balance.

Tariffs are also imposed on imported goods to help local industry. In a young country like Australia local factories such as machine factories, woollen and paper mills, &c., could not exist if they had to compete against foreign countries. Foreign countries have old, well-established factories with the latest machinery, and can,

therefore, produce goods much cheaper than the local factories In the competition of Free Trade the local industry would be killed. It has been found an advantage in a new country like Australia to protect secondary industries. These industries provide much employment, and this in return supplies a local market for meat, wheat, butter, eggs, &c. It has often been said that the city could not exist without the country, but it is equally true that the country would be in a very bad way were it not for the thickly populated cities and the markets for farm produce that result therefrom.

The third reason for imposing tariffs is to avoid the dumping of foreign goods. It has happened that a monopoly, for example, has shipped its surplus goods to a foreign country and there sold them at less than cost price. This process is known as dumping, and it is easy to see how such a thing could ruin a local industry. Consider what would happen if a foreign country dumped its surplus wheat in Australia. There would not be much left of our farming industry.

Free Trade would, of course, make many things cheaper, for example, sugar, tobacco, cornsacks, tractors, machinery, petrol, &c.. and would seem at first sight to be of value, especially to the farming community. But that may not be the case. It may give cheaper implements but ruin the markets for our products. If the factories had to close the prices of such things as eggs, butter, meat, fruit, vegetables, sugar cane, &c., would immediately slump.

The effects of a tariff may be given as the following:—Local industry is preserved and so markets for farm produce, increased employment, revenue for the Government, which all help to pay, foreign goods are kept out. The disadvantages are:—Local goods, for example, go up to the price of the imported article, the local article may be inferior to the foreign one, by restricting imports from other countries we also lessen our markets abroad. Examples of this are barley in Belgium, and quite recently our markets in Fiji, because Australia has placed too high a tariff on Fiji bananas. Tariffs cause prices to rise, since the dealer will always pass on the tax if he can to the consumer. Tariffs have advantages as well as disadvantages, and a country like Australia would be wise to retain some tariffs at least.

OBSERVANCE OF PRACTICAL FARMING.

[By J. G. Schuppan, Wilmington.]

Much can be said in the direction of practical farming, and experiments and observations have now led me to believe that farming in the Northern areas is only a gamble which depends more on luck that direct practical work.

I have seen poor crops on well-worked fallow, and also good crops on poorly-worked land It is important for the man on the land to study the climatic conditions and character of soils which vary considerably in one district. The working that would prove a success on one soil is likely to fail on another farm.

Climatic Conditions.—My experience has proved that where there is a rainfall of under 8in. per year fallow should not be worked in spring, but any weeds that make an appearance kept down with sheep. This, with an additional working before seeding gives best results. If the rainfall is above 8in. per year I advocate working the land in spring, providing conditions are favourable. It is a well-known fact that just as much harm can be done to some soil by over working as under working.

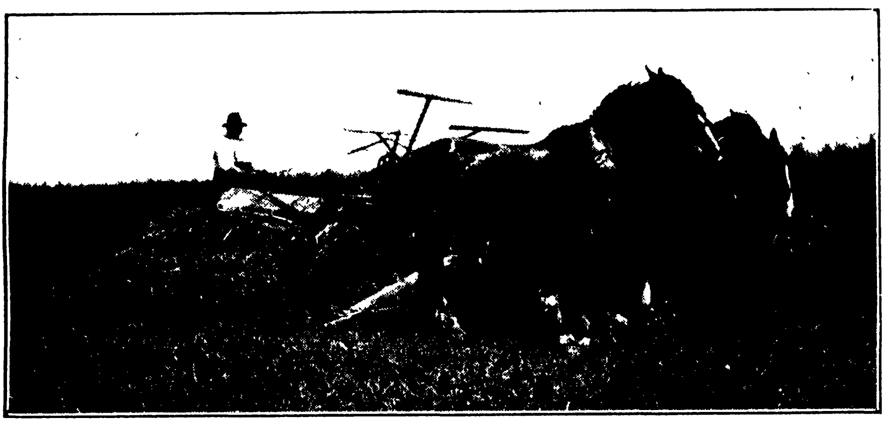
I have always been a believer in proper cultivation, and for this reason. In 1923, with 15in. of rain in that season, 500 acres were fallowed of which 50 acres remained uncultivated. The land was sown in 1924, during which year

[*Papers Read at Conferences.*]

12½ins. of rain fell. The yield on 450 acres was from 15bush. to 18bush.; the 50 acres not cultivated in spring received an extra cultivation at seeding and yielded 24bush, showing a difference of 6bush. to the latter method.

I tried further experiments. One field of 100 acres ploughed in 1924 on 12½in. of rain was given eight different workings; ploughing 5in. deep and harrowed soon after, cultivated twice in spring with a tine cultivator, again worked in February with a disc, cultivated, drilled, and harrowed at the end of April and beginning of May. This turned out a great disappointment, only yielding a 9bush. crop. The rest of the fallow, which received five workings, returned from 12bush. to 15bush. This led me to believe that the soil was overworked and became waterlogged. As these figures are taken from a fair rainfall for our district, I would also refer to a low rainfall, for most of us think that we can conserve moisture by spring cultivation no matter how low the rainfall.

Referring to 1927:—Four fields of fallow land were sown at the same time with the same variety of wheat and amount of super. No 1 field of 100 acres was ploughed in June and July, harrowed and cultivated in September, 1926, on



an 8.03in. rainfall, and returned 9bush. No. 2 field was fallowed in August, and not worked until seeding, weeds being kept down with sheep, and it returned 12bush.

The same season 15 acres in a rather dry condition were fallowed with a tine cultivator, and 90 acres ploughed after rain. In 1928 both plots were put in dry. The rain for that year was 6.58in. Results:—15 acres shallow worked gave 3bush. per acre; 90 acres of well ploughed fallow returned ½bush. to the acre. Following these figures will prove that very little can be done so far as conserving moisture with a rainfall below 8in. is concerned, especially with a run of bad seasons following.

Referring back to 1894, with a rainfall of 15.45in., of which 4.74in. fell in December. In such a case it is apparent that moisture was carried forward to 1895, when the rainfall was 8.39in., and the growing period from April-November received 7.58in., giving a return of 7bush. to the acre, while 1896, also with 8.07in. of rain, only produced ½bush. to the acre; 1902, also with 8.98in. of rain—6.83 falling during the growing period—produced 7bush.; 1914, with 8.59in., of which the growing period only received 4.56in., returned nil.

These figures show plainly that it takes about 7in. of rain to produce about 7bush. of wheat, providing that dry seasons do not follow too closely on one another.

[*Papers Read at Conferences.*]

Crop Competitions.

Much credit is due both to the Departmental Instructors, as well as the competitors, yet it appears to me, following the figures quoted, that the Instructors have overlooked various important points; that is, to give every man an equal chance under the present system is impossible, because different localities in one district would receive probably 2in. more rain annually. Figures prove that with an additional 10in. of rain more could be done, both from a production point of view as well as for the destruction of weeds. If rainfall was taken more into consideration it would give the instructors a little more work so far as judging was concerned, but the difference in crops taken into comparison would not be so great as at present. More interest would be taken by all farmers because the competitions now interest only a few in a sure rainfall locality.

FARMING AS A BUSINESS PROPOSITION.

[By S. McCallum, Willowie.]

Farming has been one of the most important industries throughout the whole world for practically all time. But it is only of recent years that it has become a business proposition. In years gone by the farmer went out and tilled his land, sowed the grain, and harvested it by primitive, crude methods which involved very little or no expense. To-day farming is quite a different work; unless a farmer has capital to invest in various classes of implements and farming tools it is practically useless to try and win success. Thus we see that it becomes necessary to invest a large amount of capital in the farm. This makes farming a business proposition.

In this paper I wish to compare the business of farming with that of money invested in the trading banks or bonds. Suppose we have two young men with £1,500 of capital. One decides to invest his money in the bank as his business proposition. He receives a return of 3 per cent. per annum for it. While this money is earning interest for him he is employed and receives the standard living wage which under ordinary circumstances is sufficient to provide for his home requirements and pay all expenses. Thus it is not necessary for him to draw the annual interest on his investment year by year. Through the advantage of compound interest at the end of 23 years his money has doubled itself, making £3,000 in the place of £1,500 originally invested. The money he invested in the bank is therefore a sound and safe business proposition, and he goes on increasing in wealth as the years roll by.

The other young man invests his money in a farm and farming plant. Approximately he pays £500 for plant, and the balance of £1,000 is paid as a deposit on the purchase price of his farm. Suppose he buys 1,000 acres at £2 per acre. This leaves a mortgage of £1,000 on the land, and he is responsible for the interest thereon year by year, and although the depositor only receives 3 per cent. for his money the borrower pays 5 per cent. per annum. If his business proposition is safe and sound, as that of his companion's, he should not only gain £1,500 in the 23 years, but he should receive an equivalent to wages both for himself and his family. Then, too, he must invest further capital in the purchase of seed wheat, super, working expenses, and other necessary improvements, such as fencing, &c. This money must also return a bank rate of interest yearly to place him on a level with his companion.

Rates and Taxes.

He is called upon by the Government to pay tribute to a much larger degree. The ordinary worker has the means of travel provided for him by means of train, tram, and bus, and he pays a very small fee to travel thereby. The farmer

has to provide his own car to travel with, then he is called upon to pay on an average £8 per year to register it before he can legally go out on the roads. He has also to pay 10s. per year to have a licence to drive his car. These two items alone amount to nearly 3s. 6d. per week; then he has the expense of petrol on which he pays a tax; he buys oil, and has all the unavoidable expenses of wear and tear. His land also has a tax placed upon it; he has to pay land tax, district council rates, and if he is adjoining a water main—though he may have an abundance of water without it—he is rated for water which amounts to £16 13s. 4d. or more.

In the event of a drought or failure of return he is forced to draw upon his reserves. If under circumstances such as we are passing through today, year after year he is forced to do so. This is bad business, but even worse is the fact that immediately he receives an income—though he may have lost thousands of pounds previously—he is forced to pay an income tax. This is not right, and it places him under a heavy penalty compared with his fellow investor.

To-day farming as a business proposition is a complete failure, and many a farmer who invested his money in the farming industry has been completely ruined, while his companion who invested in the bank or bonds has been steadily increasing in wealth. All interest paid to investors must be paid from the return received from products. Otherwise we are robbing one investor to pay another's interest. This has been going on in the farming industry for years, with the result that instead of the farmer increasing his capital as the years roll by in a similar manner to the city investor, he has been gradually paying out his original capital. Is it any wonder, then, that the farmer is growing desperate and despondent? Realising the enormous losses that farmers have experienced during recent years, they know full well that it is impossible for their sons to launch out upon the land until some great change takes place. Our young men are very discouraged and disappointed, but most of them are working on, hand in hand with their parents, bravely carrying on what seems at present a fated industry.

Women on the Farm.

Still more noble and courageous is the spirit of our womenfolk; not only are they keeping the home together by their faithful toil and rigid economy, but they are working overtime milking cows, attending to fowls and various other duties which a farm provides. All they expect to get is enough to provide food and clothing for their families. Finally, let me warn our young men who have capital to invest to consider well before taking a venture, and beware of farming as a business proposition. For it is in reality, under present conditions, nothing but a losing business proposition. Let us as farmers be awake to our great disabilities, and, although we must continue to preserve and carry the industry through these adverse and severe conditions, keep a keen watch on those who are day by day seeking to draw out the very lifeblood of the farmer, and we shall eventually prevail against them.

IMPROVING THE STANDARD SAMPLE OF SOUTH AUSTRALIAN WHEAT.

[By E. H. Hampel, Wilmington.]

The matter of the standard sample of f.a.q. wheat in South Australia is one that should be the concern of every wheatgrower. There has been a steady deterioration in the standard during the past few years which has resulted in some depreciation in the regard in which South Australian wheat is held by overseas' buyers, and consequently a corresponding decline in its relative value.

[*Papers Read at Conferences.*]

Recently as much as 1s. per quarter (1½d. per bushel) more has been secured for Western Australian wheat in the London market than could be obtained for South Australian shipments in a similar position. This was due to the superior quality of the Western Australian sample of grain, which has been consistently good during the past few years.

The following schedule shows the weights of the respective standard samples of the various States since 1924-25; it will be observed that the Western Australian sample has been most consistent, and this feature is no doubt responsible in a large measure for the high reputation it has earned with the British and Continental millers:—

Season.	N.S.W. Lbs.	Vic. Lbs.	S.A. Lbs.	W.A. Lbs.
1924-25	60¼	60½	62	62½
1925-26	62¼	62½	61½	62
1926-27	61¼	61½	61	61¾
1927-28	60¼	61¾	62	61½
1928-29	63	61¾	62	61½
1929-30	61¾	62	60½	62½
1930-31	59½*	58½	60	62½
1931-32	61½*	62¾	61½	61¾
1932-33	61¼	62	60	62
1933-34	59*	60	60	61½

*During seasons 1930-31, 1931-32, and 1933-34 in New South Wales special second quality standards were struck at 56½lbs., 58lbs., and 55lbs. respectively, such standards being necessary to cover quantities of wheat damaged by rain at harvest time.

While climatic conditions without doubt affect to a great extent the season's sample, it is also indisputable that the growers themselves cannot be freed from responsibility. Year by year the quality of the standard sample suffers materially owing to the presence of smut-affected wheat and foreign matter, such as smut ball, barley, oats, star thistle, mallee leaf, &c., much, if not all, of which is within the power of farmers to exercise some measure of control.

The unfortunate part of the matter is that the presence of inferior wheat or foreign matter in the sample has the effect of reducing the value of the whole of the wheat in the State, so that the farmer who produces a good, clean sample carries part of the loss incurred by the less careful grower.

One of the most serious defects in the South Australian sample is the presence of star thistle. This is particularly obnoxious to flour millers, who will not accept wheat affected with it on account of the extreme difficulty in removing it. It is not susceptible to the usual methods of wheat cleaning, and the millers' machinery will not remove it. Farmers should take particular pains to keep their land free from this weed.

Smut affected wheat and smut ball also have a detrimental effect on the standard quality. Effective pickling of seed is essential if this disability is to be lessened.

Farmers whose wheat is inferior frequently are of opinion that the dockages imposed by wheat buyers are excessive, and represent more than the difference between their particular sample and one of fair average quality. In this regard it must be remembered that the buyer must make provision for the additional costs of handling, as well as for the inferior quality of the wheat. When inferior wheat is found amongst the contents of a truck at a mill or at ship's side it becomes necessary to handle it several times, and each handling costs money. First, it must be reloaded into a truck or trolly, then carted to a store, unloaded, stacked, and eventually unstacked, loaded to trollies, and carted to the ultimate buyer. By this time it is possible that the costs have been increased by anything up to 3d. a bushel, which amount must be added to the loss in value, due to inferior quality.

[*Papers Read at Conferences.*]

Grading.

It is considered by some that the difficulty regarding the standard sample could be overcome if the wheat were graded before shipment. It is most doubtful whether the benefits which would accrue from the introduction of a thorough system of grading Australian wheat would compensate for the cost of installation and maintenance. In any case such a system could only be operated as a part of a complete system of bulk handling, but it is significant that grading machinery installed in conjunction with some of the country wheat silos in New South Wales is not used.

The grading system in vogue in the United States of America and Canada is very complicated, and hundreds of differing grades of wheat are produced. There is a marked difference in value between the higher and lower grades, and as relatively little of the wheat as a rule reaches one of the high grades the advantage gained may not be as great as would at first appear. The various grades are fixed according to certain defined milling qualities, such as moisture and gluten content, &c., the different classes of grain are kept separate. A thorough system of grading requires a great deal more to be done than the mere elimination of inferior grain and foreign matter. No adequate comparison can be made between North American and Australian conditions because of the difference in climate and other factors.

A trial shipment of cleaned wheat was made by the South Australian Co-operative Wheat Pools Limited in 1933 in order to establish whether it would be a practical proposition to ship wheat thus treated. The experiment showed that, apart from the cost of treating the wheat and additional handlings, which was quite considerable, the additional value the wheat acquired did not compensate for the loss in weight and the reduced value of the screenings and waste matter which resulted from the process. The final result was a loss equivalent to ½d. a bushel on the quantity treated, apart from the additional cost previously mentioned.

If cleaning is to be done it could probably be most economically performed on the farms, where there would be an outlet for the screenings, and extra handling reduced to a minimum and some cost avoided. It still remains doubtful, however, even if the work was done on the farms, whether the result to the individual farmer would be worth the effort, although, if delivery of thoroughly clean wheat were to become general, there would be a distinct improvement in the standard sample, which would doubtless be reflected in the relative value overseas.

Because of the lack of incentive, farmers do not utilise to the best advantage the engineering skill used in the construction of Australian harvesting machinery. Because of the excellence of this machinery it is believed—after allowing for difficulties inseparable from field work—that the grain can be so "dressed" or cleaned that no more than 1 per cent. of screenings or other unmillable material need be left in it. The f.a.q. standard allows for nearly four times this amount, and in consequence many farmers now cover up or remove the tailing screens from their harvesters, whilst the more unscrupulous ones allow them to become choked, and thus deliberately lower the commercial value of our main agricultural product by including a much larger percentage of unmillable material.

The most obvious avenue for the improvement of the South Australian wheat standard lies in more careful farming, particularly as regards selection and preparation of seed to prevent smut and other diseases, and efficient cultivation to eliminate weeds and foreign growths.

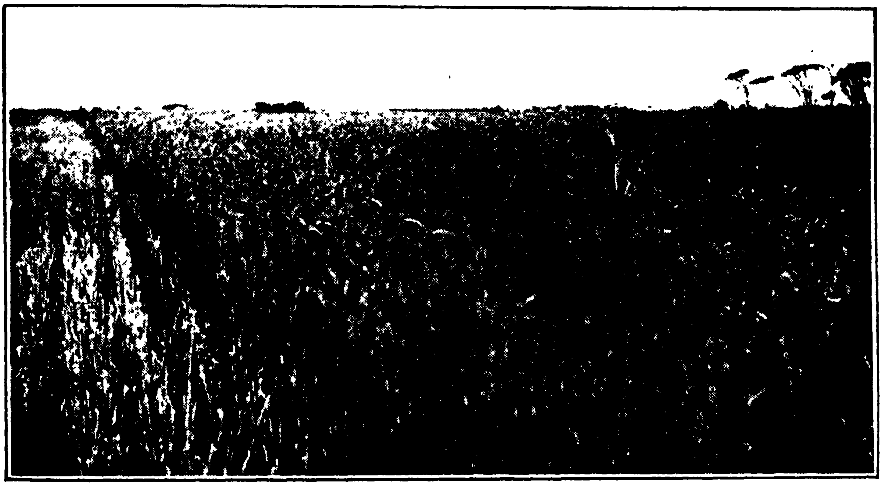
Milling Qualities.

There are, however, other avenues which must be followed if the general standard of Australian wheat is to be improved. In particular, it is essential that more attention should be paid to the milling and baking qualities of the wheat. In the

past scientific investigation in Australia has been principally in the direction of increasing the yield per acre, without paying much regard to the quality of the grain produced, or whether it was suitable for bread-making or of the quality particularly required by overseas buyers. South Australia is fortunate in having as Minister of Agriculture the Hon. A. P. Blesing, one who brings to the position a practical knowledge of farming. The improvement of the wheat standard has had the particular attention of the Minister, who has made frequent public reference to the need for improvement, and he is very keen to discover every practical means of attaining this objective.

The Principal of the Roseworthy Agricultural College (Dr. A. R. Callaghan) is paying particular attention to this factor in planning the crossing experiments conducted at the College. In a recent report Dr. Callaghan stated that the main objectives in planning the crosses were, in order of importance:—

1. Improvement in the baking quality of commercial Australian wheats.
2. Increasing disease resistance of commercial varieties, thereby increasing yield.



A Crop of Sword Wheat.

3. Breeding for short, strong straw.
4. Breeding for improved holding capacities in varieties which show a tendency to shatter.
5. To increase size and fulness of head and fill sterile spikelets.
6. Breeding for drought resistance.

The Department of Agriculture has been giving the matter of improved milling wheat close attention, and in the January number of the *Journal of Agriculture* an interesting article appeared, which referred to a report by Mr. S. R. Cowley, who personally investigated trade conditions in the Orient. Mr. Cowley found that the flour trade to Japan, China, the Dutch Indies, and other places in the East was becoming increasingly confined to Eastern Canada and the United States of America, particularly the former. The reason was found to be the superior quality of the North American flour for baking purposes, as compared with the Australian article; and this superior quality outweighed any price advantage there might have been in favour of Australian.

[Papers Read at Conferences.]

One of the principal complaints regarding Australian wheat and flour was that it lacked uniformity, whereas the quality and content of gluten, moisture content, and colour of the North American products were consistent. After seeing practical tests and thoroughly investigating local conditions, Mr. Cowley came to the conclusion that Eastern buyers would never be prepared to accept wheat or flour of irregular and unstandardised quality. Under the present f.a.q. system in Australia, where grain of many different qualities is mixed indiscriminately, it is impossible for sellers to guarantee any particular standard. Mr. Cowley emphasised the fact that a high gluten content was not essential to secure favour with Eastern buyers, but a uniform content was indispenable.

It is pointed out in the article that good milling wheats generally yield lower crops than the poorer types of milling wheat; consequently wheat continues to be grown in Australia for its capacity to yield bushels per acre rather than for its suitability for bread-making. This was likely to continue until a higher price could be secured by farmers for wheat of superior milling quality.

The article concludes thus:—"Much of the trade in flour in New Zealand lost by Australia to Canada has been due to the lack of uniformity in the quality of the shipments. As a result of this lack of uniformity, New Zealand bakers turned their attention to Canadian wheat. The result has been that New Zealand bakers and millers will not easily, even for price, revert to their former large use of Australian wheat and flour until such time that Australia can deliver more uniform quality. In addition to this, New Zealand, through its research scheme, has eliminated, through the control of the field officers of the Agricultural Department, many wheats which were unsuitable for bread-making, though prolific yielders of bushels per acre. Wheatgrowers have happily co-ordinated with the millers and bakers, and, with the aid of the Canadian cerealist engaged under the Wheat Research Institute, millers have been able to devise methods of controlling their grists, which give greater standardisation."

The method of arriving at the standard sample of wheat in South Australia each year may not be known to all farmers. It is customary early in each January for the Grain Trade Section of the Chamber of Commerce to ask the principal wheat handling firms to secure from their various agencies throughout the country representative samples of the wheat in the respective stacks. It is understood that the samples shall be a fair average of the wheat received; consequently they will include a proportion of smut-affected and light-weight wheat, foreign matter, etc. The whole of the samples received, numbering several hundreds, are thoroughly mixed together, and the resultant mixture represents the standard sample for the season. A bushel measure is filled with this wheat and weighed, and that weight declared to be the standard weight for the season. The weight for the 1933-34 season so established was 60lbs. to the bushel measure. It is important to recognise that the weight of the standard sample has nothing to do with the weight of wheat which represents a bushel for buying and selling purposes. This is always 60lbs., but the standard fixed by the Chamber of Commerce each year is for the purpose of establishing quality only.

It is well for farmers to remember that if they deliver wheat of inferior quality it is possible that it will find its way into the State standard sample, and thus be the means of assisting to reduce the standard by which the whole of the wheat in the State is sold.

The Chamber of Commerce issues samples of the season's wheat in sealed bags of various sizes. These are despatched to all parts of the world, where they are examined by prospective wheat buyers, who thus are able to form their own opinions as to the value of the wheat from South Australia. Every sale of that season's wheat whether at home or overseas—must conform to the official standard.

If it differs in any respect it may be subject to a dockage, which must be borne by the sellers. Most dockages on overseas sales are settled by special arbitrators at the Baltic Exchange in London. Dockage on a cargo of wheat may run into as much as £500 to £1,000, or even more.

South Australian millers are equally anxious to secure wheat with better milling qualities as are those in other countries, and a comprehensive study of the question was contributed to the *Journal of Agriculture* by Mr. G. L. Chinner, a miller, of Loxton, and appeared in the issue of November, 1933. Mr. Chinner emphasised the necessity for a consistent gluten content, and hinted that South Australian millers may be prepared to offer some premium for wheat of the desired quality; this would, without doubt, encourage its production by farmers. Mr. Chinner's conclusions were generally along the same lines as those of Mr. Cowley, referred to elsewhere in this paper.

This is an era of intense competition, and the future of the wheatgrowing industry in Australia appears far from satisfactory. It certainly appears that for some years to come there will be fierce rivalry amongst the various wheat exporting countries for the limited trade to Europe and other importing countries. It is obvious that when selling competition is keen quality will be of paramount importance, and the time may not be far distant when wheat of inferior quality will be not merely subject to a decreased value, but quite unsaleable. Farmers will be doing well, both individually and collectively, if they extend every effort towards improving the quality of the grain they produce, for it is a matter of national importance.

HANDLING AND CARE OF A SMALL FLOCK, ETC.

[By G. FRAZER, Wilmington.]

It should be understood that this paper is to assist the beginner, and not the man of wide experience, although perhaps some others older than the young farmer or grazier of to-day may receive a little interest also. First, it is presumed that the young man has a farm or grazing block which is well fenced, preferably with netting.

PURCHASING EWES.

The breeder first needs a flock of Merino ewes—an even line, with sound mouths—from a station or a well-known breeder. Buying 2-toothed ewes is a gamble, as a rule, excepting during a drought year, when some people may have to dispose of their young ewes.

Buy ewes with plain bodies, as large-framed as possible. Avoid ewes with folds over the tail and in the crutch, and do not have too much leather on the neck, nor too heavy a flank.

PURCHASING SIRES.

If you can obtain a good line, and the property is well watered with wells or dams, next purchase or hire some good sires and mate to these ewes. This is very important, and for the sake of £1 or 10s. a good sire should not be overlooked. The next step is to mate the ewes at a suitable time, so that they lamb while there is a picking of green feed for the lambs. Sometimes early lambs are the best; sometimes late lambs. Taking an average over many years, May is one of the best months in the writer's opinion.

When mating rams, always clear the wool away from the horns, and swab with fairly strong dip to prevent fly-blow. Crutch all ewes about a month to two weeks before lambing.

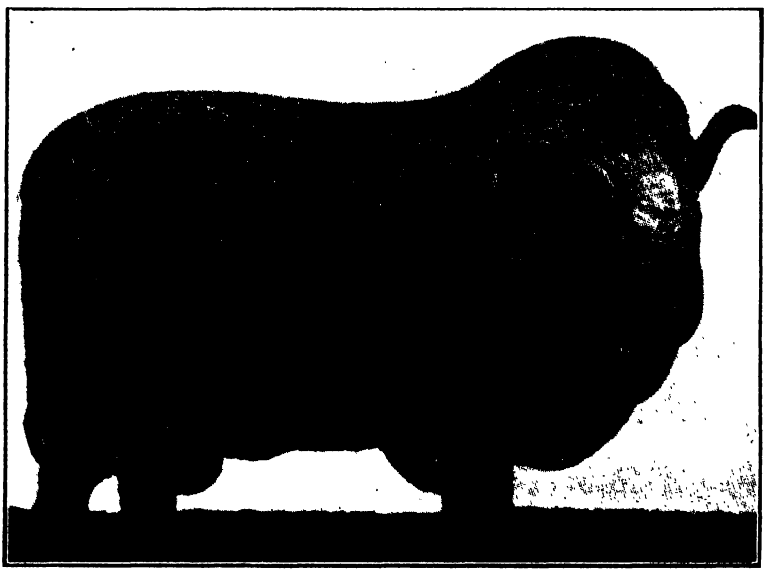
[*Papers Read at Conferences.*]

LAMBING.

When the ewes start lambing watch for flies; they are a terrible pest during lambing. If a ewe goes down on her side or back overnight lift her up until she can balance on all legs. Crows and hawks are troublesome at lambing time. Rabbit traps are very useful for catching either. Foxes are the greatest enemy of the flockmaser. It may not be that foxes kill so many lambs, but they frighten a number of lambs away from the mothers, especially young ewes.

Tail all lambs with a knife, not with a searing iron, and yard the ewes and lambs for marking the night before. When shifting ewes and lambs from one paddock to another do not force them through a gate; start a few, and let them draw through on their own. Many practical sheepmen advise pulling out the wires in a fence for a couple of panels and allow them go through that opening on their own accord.

If possible, do not permit the rams to run with the flock all the year; put them in a small paddock by themselves and hand-feed them. Sires should be cared for during the whole year, not only during mating time.



A Typical Merino Ram.

When the ewes are 1½ years old have them classed, preferably by the breeder from whom the rams were purchased, providing the sires have turned out satisfactory. If classing them yourself dispose of ewes with cow hocks, open backs, clear legs and face—these generally carry a light type of wool—wrinkly around the tail or crutch, those with very narrow shoulders, wool blind, and any with very small frames; and try and have in mind one type, and aim to produce it. Each year should see an improvement, providing you keep to the one type of sire from the same breeder.

Always have drafting yards running uphill, if possible. Yards running to the shed for shearing should, if possible, run uphill. If sheep are hard to get into the woolshed, catch a sheep and tie it up in the shed with a little rope; the rest will generally go in easily.

I have fed with success wheaten hay, barley, oats, baled lucerne and Meggitt's meal, but all are expensive if they have to be continued for any length of time.

Baled lucerne is one of the best fodders for young lambs in particular. Dry sheep may be fed on any of the above foods, but it is a different question regarding lambing ewes when it comes to making milk. This is our greatest drawback.

After shearing dipping should be done; if not for lice or tick in your flock it will help the sheep against lousy or ticky sheep belonging to someone else.

When weaning lambs put them in a paddock that has a dam of water, rather than a trough at a well. Lambs never like drinking out of troughs; also use paddock with the least grass seeds.

One often notices how roughly some sheep are handled. In sale yards some men catch a sheep by the leg and turn it over on the ground. The only time I would advise catching a sheep this way is when it is fly-blown; catch it any way so long as it is freed from this pest. Otherwise, catch a sheep around the neck and sit it down comfortably; if possible, not on the ground, but on a bag. This makes a protection from dust in the wool. Do not catch sheep out in the paddock except fly-blown; it makes them wild, and the quieter they are the better they thrive.

A Few Don'ts.

Don't use sharp sticks; cover them with a bit of bag.

Don't have half a dozen dogs in the yard; one dog can do the work much quieter and better.

Don't use sires from a breeder whose rams have proved unsatisfactory.

Don't rush sheep through a dip; let them go through steadily, and, if possible, dry under cover.

Don't rush sheep from the back of the yard; work against the way they are going.

Don't hang sheepskins over a rail; peg them out on a floor. This keeps out all the edges, and they dry better and quicker.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on August 29th, there being present Messrs. A. J. Cooke (Chairman), A. M. Dawkins, J. W. Sandford, F. Coleman, P. J. Baily, H. N. Wicks, A. L. McEwin, A. J. Koch, Professor A. J. Perkins, Dr. A. E. V. Richardson, and H. C. Pritchard (Secretary). An apology was received from Mr. J. B. Murdoch.

Appointment of Chairman.—In view of the services which he had rendered to the Board, Mr. Cooke was unanimously requested to continue as Chairman until the question of his resignation could be further considered. Mr. Cooke agreed.

New Branch.—Conditional approval was given to the formation of a Women's Branch at Boor's Plains, with 17 foundation members.

Branches to be Closed.—It was decided to close the Tailem Bend and Kimba Branches.

Life Membership.—On the proposal of Mr. Wicks, seconded by Mr. Sandford, it was decided that Mr. W. L. Summers should be presented with a special Life Membership Certificate of the Agricultural Bureau, and that the presentation would be made at the Annual Congress.

Life Membership Certificates were also granted to Messrs. J. Kakoschke and J. H. Jericho (Lameroo), S. C. Billinghurst (Minnipa), J. Pope and N. Grace (Watervale), and C. Halliday (Morchard).

Delegates' Attendance at Congress.—It was decided that each delegate appointed to represent his Branch at Congress must attend at least 50 per cent. of the number of sessions otherwise he would be called upon to refund the amount of his fare to Adelaide.

New Members.—The following names were added to the rolls of existing Branches:—Kilkerran—A. Sawade; Tantanoola Women's—Mrs. W. Stafford, Mrs. W. Pycroft; Wilkawatt Women's—Mesdames W. Eime, A. Sumsion, W. R. Neville, E. W. Brooker, P. Gregurke, A. W. Bates; Milang—K. Turvey; Minnipa—W. J. Black, W. Crowther, J. Barnes, H. E. Broad; Narridy—J. W. Eagle; Morchard Women's—Mrs. R. F Brown, Mrs. W. Martin, Miss Joyce Martin; Alawoona—W. Watts, R. M. Koch, A. Pengilly, jun.; Koonunga—C. Bartsch, A. H. Falkenberg; Macclesfield—Alex. Read, A. Lane, Alex. Smith; Brinkley—E. A. Jones; Gladstone—E. E. Clothier, J. L. Potter, H. M. Wehr; Millicent Women's—Miss T. M. Thompson; Taragoro—L. Rudland, D. Crabb; Rendelsham Women's—Mrs. C. Stratford; Petina—A. E. Daniels, M. G. Prescott; Yurgo—A. G. L. Bampton, E. Kelly; Lenswood and Forest Range—S. Filsell, M. Mason, H. Jones; Barmera—R. M. Simes, C. T. Leaney, E. Crocker, S. A. W. Farmer, H. O. W. Short, H. Jeffries, G. Manning, R. H. Davidson, L. de Fontenay, G. Jones; Buchanan—E. N. Rohde; Clare Women's—Mesdames M. Phyllis, C. Gordon, G. Coles; Penwortham—P. Modystach, J. Chynoweth; Pinnaroo—C. H. B. Ross, A. E. Ross; Kalangadoo—D. Cowell, T. K. Hemmings, C. E. Leader; Mypolonga—A. E. Milde, H. E. Daenke; Appila—C. Bottrall; Narridy—J. M. Smith; Greenock—E. R. Radford, E. J. Helbig; Gladstone Women's—Mrs. E. E. Clothier, Miss Milligan, Mrs. Pearce, Mrs. T. Ballantyne, Miss J. Ballantyne, Mrs. W. Ballantyne, Mrs. Alf. Harris; Tintinara—E. Bower, W. Worral, H. R. Becker, H. S. Williams; McLaren Flat—Robt. Guthrie, M. Kelly, Robt. Deane; Blackwood—H. A. Baust, A. F. Baust; Koolunga—T. M. G. Cameron; Snowtown Women's—Mrs. J. B. Kirchner, Mrs. P. O'Donnell, Mrs. T. O'Donnell, Miss K. O'Donnell; Saddleworth Women's—Miss M. S. Noble; Jervois—F. L. Stans, A. Rothe, C. Schultz; McLaren Flat Women's—Mrs. P. Penney, Mrs. Bert Elliott, Mrs. A. T. Nicolle, Mrs. Jas. Powell; Taplan—J. C. Kelly, R. Moffatt, W. Moffatt, T. Schwerdt, C. Schwerdt; Parrakie—P. Ross; Tantanoola—L. B. Medhurst, H. Bunston; Watervale—D. A. Munro; Mangalo Women's—Mrs. Gaston; Weavers—W. G. Agnew; Cummins—Bert Hinton; Clarendon—F. H. Menz, C. G. Easton; Echunga—R. Perry, H. E. Berry, C. F. Mead; A. H. Harvey, F. Mincham, Lloyd Hampton,

M. Kavanagh, G. Edmonds, H. J. Causby; Belalie Women's—Miss E. Mitchell; Balhannah—T. Drewett, F. Ball, J. R. Pfeiffer, H. L. Pfeiffer, S. H. G. Grivell, A. F. Altmann; Balumbah—T. M. Wright; Kyancutta—W. J. Rorke, T. McGuinness; Kelly—F. K. Parsons, G. T. Parsons, Jas. Liddicoat, Jas. M. McMurtrie, T. W. Hutchens, R. G. Hall, R. J. Beinke, F. J. Wakelin; Beetaloo Valley—C. Holmes; Mount Compass—F. N. Simpson; Kalangadoo Women's—Mrs. T. Hemmings.

Bureau Statistics.—Number of members, 7,610; number of Branches, 337.

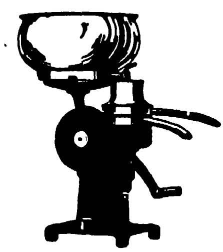
Several items were discussed in Committee.

BREEDING, FEEDING, AND DISEASES OF DAIRY CATTLE.

The Library of the Department of Agriculture acknowledges the receipt of the July, 1934, issue of *The Veterinary Journal.* This number is devoted to the breeding, feeding, and diseases of dairy cattle, and copies can be obtained from the publishers, Messrs. Baillière, Tindall & Cox, Henrietta Street, Covent Gardens, London, W.C.2. Price 2s. 2d., post free.

WIMMERA RYE GRASS ON EYRE'S PENINSULA.

In his report on the agricultural prospects at the end of August, Mr. H. D. Adams (Agricultural Instructor for Lower Eyre's Peninsula) says that many farmers who sowed sections of their holdings with Wimmera Rye Grass and Lucerne this year have reported good germination and growth of many fine plots of Rye Grass. That of Mr. G. Pasper, in the hundred of Butler, is outstanding and equal to anything he (Mr. Adams) had seen in this or any other State, and gives promise of a heavy yield of seed, for which purpose it was sown



DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & CO., LIMITED, reported on September 4th, 1934:—

BUTTER.—Conditions in connection with dairying throughout August improved somewhat as there were several periods when general rains were received. The precipitations, however, were only light, but were sufficient to keep the pastures going, and, consequently, the supplies of cream and butter showed a forward movement. Production in this State, however, is still very much lower than last season, and heavy subsoil soaking rains are required to ensure late spring and summer feed. Trade generally has been well maintained, and, although the London market has shown very little fluctuation, the local print trade was well maintained, and the prices paid to the farmers for butterfat were satisfactory. At the date of report choicest Kangaroo butter in London was selling at 74s. per cwt., and the following were the local prices:—Choicest creamery fresh butter in bulk, 1s. per lb.; prints and delivery extra. (These prices are subject to stabilisation levies.) Store and collectors' lots, 6½d. to 7½d. per lb. at store door, according to quality.

CHEESE.—The South-Eastern factories sent forward ample consignments of new cheese each week for local and Westralian trade, but the turnover was somewhat disappointing, as many of the larger retail distributors had stocks in cold store which they had purchased earlier in the year at lower prices. However, sales are now moving a little more freely. In the meantime the factories are making their surplus into export-size cheese, and these will be shipped to London from time to time. The present market rates for local cheese are as follows:—Large and medium, 8¼d. to 8¾d. per lb.; loaf, 8¾d. to 9¼d. per lb.; semi-matured and matured, 8¾d. to 9½d. per lb.

EGGS.—The season has been very backward as regards egg production, due largely to the unseasonably dry conditions which ruled. However, the supplies are coming along more freely, and, as exporting is now in full swing, rates have come back to export parity. Market rates are:—Ordinary country eggs, fair average quality, 8½d. per dozen net; export quality, 1⅞oz. and over, up to 10½d. per dozen net.

BACON.—Manufacturers consigned ample quantities each week for all requirements, and the local trade was well supplied. Some interstate trade was also done. Hams continued slow of sale, but until the warmer weather sets in this must be expected. Quotations are:—Best quality sides, 9d. to 9½d. per lb.; middles, 10d. to 10½d. per lb.; rolls, 7½d. to 8d.; hams, 11d. to 11½d.; cooked, 1s. 1½d. to 1s. 2d. per lb. Lard, prints, 5½d. per lb.

ALMONDS.—Most growers have, ere this, considerably reduced stocks, but odd consignments came along in the open markets each week and ready sales were effected. Kernels were hardly in such good request as earlier in the year, but trade is now showing a little improvement in these. Softshells and Brandis, 8½d. to 9d. per lb.; hardshells, 5½d. per lb.; kernels, 1s. 11d. to 2s. per lb.

HONEY.—The turnover in this commodity has continued disappointing, although nice quality consignments were available. Some odd interstate shipments were made, but these, together with the local trade, were insufficient to clear stocks from week to week. Prime quality clear extracted, 3d. to 3½d. per lb.; lower grades, 2d. to 2½d. per lb.

BEESWAX.—All consignments met with ready sale; 1s. 4d. to 1s. 4½d. per lb., according to quality.

POTATOES.—Prime Victorian Carmens, 9s. per cwt.

ONIONS.—Brown Spanish, 9s. per cwt.

LIVE POULTRY.—With the near approach of the Duke of Gloucester's visit and the Royal Agricultural Show, it is expected that there will be a large influx of visitors to the city, and, in anticipation of this, poulterers are now buying heavily and having stocks placed away in refrigerators to meet the extra demand. Sales, therefore, have been very brisk and values have moved forward. We advise consigning. Crates loaned on application. The following are the prices realised at the date of this report:—Prime roosters, 3s. 10d. to 5s.; nice-conditioned cockerels, 3s. 4d. to 3s. 9d.; fair-conditioned cockerels, 2s. 9d. to 3s. 2d.; chickens lower; heavyweight hens, 3s. 2d. to 3s. 9d.; medium hens, 2s. 6d. to 3s.; light hens, 2s. to 2s. 5d.; couple of pens of weedy sorts lower. Prime young Muscovy drakes, 4s. to 5s. 6d.; young Muscovy ducks, 2s. 8d. to 3s. 5d.; ordinary ducks, 1s. 9d. to 2s. 7d.; ducklings lower. Geese, 3s. 3d. to 4s. 9d.; goslings lower. Turkeys, good to prime condition, 9d. to 11½d. per lb. live weight; turkeys, fair condition, 7d. to 8d. per lb. live weight; turkeys, poor and crooked breasted, lower. Pigeons, 6½d. to 7½d. per lb.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of August, 1934, also the average precipitation for August, and the average annual rainfall.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SOUTH-EASTERN DISTRICT.

FRANCES (Average Annual Rainfall, 20.01in.).

June 20th.—Attendance, 5.

TREE PLANTING.—Mr. A. Pfitzner read the following paper:—"As land becomes more intensely stocked, which is possible since superphosphate and farming have increased its carrying capacity, there is a tendency to subdivide the pastures into smaller paddocks. This has resulted in leaving some paddocks without sufficient timber to shelter the stock from the heat of summer and cold winds. The variety of timber most planted to supplement this deficiency in this district is the sugar gum and indeed it is hard to find a better. If planted in the right conditions it makes a rapid growth and soon forms an ideal break against the seasonal elements. They are also an excellent tree to plant in the form of an avenue and where ground is subject to heavy winter traffic, for they absorb the moisture and keep the ground firm with their roots. Seedlings can be raised by placing a bough with blossoms on a sheet of paper, in December the heat will burst the nuts, and the seed can then be collected and sown in seed boxes for transplanting later, or direct into well-prepared soil where it is desired to grow them. The plants require plenty of moisture until they are well established. The Native Bull-oak makes a good shelter for stock and it is advisable that sufficient should always be left when ringing, for it is possible that there will be a shortage in the future because they take so long to grow and sheep constantly nibble off the young shoots. In some places in the north of this State, Blue Gums have been planted successfully to provide shelter, but here they would probably reseed and become a nuisance. At one time settlers in this district were obliged to plant olives and sow an acreage of grain under the conditions of their lease, with the result that there are a number of olive groves scattered about the country. The Pepper Tree is also a valuable tree about a homestead, but is often planted too close to a garden where its roots wander in search of moisture, a more suitable place for them is in the sheep yards, where they do well if railed off. Horses and cattle also have a much better chance of getting away from bots and other flies if they can move freely in a shelter plantation, until evening when they can go away to feed and water. An idle horse loses as much in condition and energy as a horse in work if it has to fight flies in an open paddock. It is impossible for sheep and cattle to give their best returns if their backs are blistered by the sun. We should protest strongly against the destruction of Bull-oak and other trees growing along roadsides and on reserves, in some cases to make way for telephone wires, and in others for firewood or because someone imagines they impoverish their land nearby. (Secretary, C. Koch.)

May 21st.—Attendance, 17.

THE PRESENT DAY PROBLEMS OF THE FARMER.—The following paper was read by Mr. E. Schilling:—"There are so many problems confronting the farmer at the present time that it is a difficult task to solve any of them. Wheat has always been the main line of production on the farm, but it has now fallen to such a low price that we have to consider whether we can make more out of our farms by paying greater attention to side-lines. For some years previous to, and up to the present time, farmers have concentrated on wheat production for the obvious reason that taking all factors into consideration wheat growing paid to concentrate upon. But as the supplies far exceed the demand, the amount of wheat which the world is able to purchase and consume has fallen far short of the amount produced. Huge surpluses of grain have forced the farmer to accept the lowest prices known in the history of the wheat industry, thus leaving no ground for hope of a better price in the near future. Our industry has to purchase its many requirements for successful production at a very inflated price, whilst we have no method of passing on costs of production to the consumer as the wheat industry is not on the same plane of favour as other protected industries. The position of the industry is that if carried on at the present stage it is no longer an occupation and a living, but a burden. As super and cornsack prices and many other items necessary on a farm do not seem to decrease much more, I am of the opinion that there is nothing else left to do but to try and cut expenses wherever possible, and pay more attention to sidelines such as sheep, lambs, dairy products and beef, bacon and poultry, as they are contributing more towards the farmer's living than the major item—wheat—is doing. Sheep will probably appeal to most, especially as wool has advanced in price, sheep also give an indirect return because they help to clean the fallow and improve the soil. Cows and a few fowls will also help to contribute towards the farmers wife's requirements. Where cows are kept, some pigs will be a help, they supply most of the household's necessary supply of meat, and secondly, if taken to the market at the right age, there is a good demand and they bring a fair price. If these sidelines are carefully attended to and the maximum of wheat grown we will be able to creep along and reap the benefit when the price of wheat rises. Do not lose heart, the wheat price will and must improve. Be there and benefit when it does." (Secretary, L. Davis.)

July 3rd.—Attendance, 18.

MIXED FARMING.—Paper read by Mr. W. L. Brown.—"There is an old maxim that the wise man never puts all his eggs into one basket. The principle still holds good although conditions have altered since that was first penned. The man who has several strings to his bow may not make a fortune so quickly as the man who concentrates upon one line of production, but his position always is safer, for he is certain of some income. This season the wheatgrower has fared badly, while those who last year devoted all their land to wool growing made remarkably large incomes in many instances. The fact cannot be ignored, however, that had a drought or disease affected their flocks, or had the bottom fallen out of the market instead of doing so well, in numerous cases they would have been badly hit financially. In so far as it means gaining a thorough knowledge of any particular subject, specialisation has much to commend it. The man who makes himself a master of dairying, sheep breeding, wheat growing, &c., is always more likely to register success with those enterprises than the man who merely dabbles in them, or changes from one to the other, simply because he lacks determination. The men who have won world-wide reputations have been those who have specialised. Make yourself a recognised authority on one subject if possible,

be it cultivation of wheat or the production of fruit, but at the same time do not overlook the possibilities of other suitable means of earning a living. What is of interest to one member of the family is not to another, and by turning aside or diverting one's attention to other lines of earning revenue adds considerably to your happiness, and encourages the interest of your children in the work of the farm. To know thoroughly one department of work is good, to turn that knowledge to the best account is better. The facilities for acquiring knowledge are open to most of us. But it is not these facilities that carry one man ahead of others, but the possession and extension of his own personal qualities. When a man has served his apprenticeship and worked hard and become skilled on the land or workshop, and becomes a professional or business man, the possession of such knowledge wakes him up, opens his eyes to possible uses of his acquired skill, widens his outlook, and establishes his standing among other men. It makes of him an individual, a strong personality, as well as a sound and constructive worker.'' (Secretary, E. Spriggs.)

BOOKKEEPING.—Mr. H. Hartmann read the following paper:—''In these days of depression reference is often made to the necessity for efficient farming methods, but this is only carrying the job half-way if the farmer does not keep books. To do this it is not necessary to have an elaborate arrangement of books for keeping an accurate account of all business transactions. Too much attention cannot be paid to the keeping of accounts of small items, for it is astounding to what figure these small amounts add up to at the end of the financial year. There are various ways of bookkeeping, but I favour the method of only keeping one fairly large book—a folioed ledger; one with the pages lettered in alphabetical order. Under the different letterings it is possible to enter the various items with the page number. In his way it is simplicity itself to look up the financial position or enter any item. Any attempt at book-keeping is quite useless if not done thoroughly. All items of receipts and expenditure must be included. Make a record of any business in the book at once, while it is still fresh in your memory. If every farmer kept a close check on all his business in this way it would do much to aid him, especially if his books tells him that any phase of farming operations is being run at a loss.'' (Secretary, C. Altmann.)

NUNKERI.

June 21st.—Attendance, 14.

CARE OF FARM HORSES.—The following paper was head by Mr. E. Harding:—"As a farmer's livelihood depends upon his horses, it behoves him to give them reasonable care and attention. A good stable, warm in winter and cool in summer, will go a long way towards keeping them in good working condition. After long spells, horses should be given only two or three hours' work for the first day or two, gradually increasing the length of time up to a full day's work. If horses are worked full days from the offset they fall away in condition. Working horses are only capable of doing a given amount of work each day. If pushed beyond this point they will not do so much work, because after a time the team will be weary and not travel so well. Allow them as much water as they will drink three times daily, and I prefer to feed with good oaten chaff; always feed enough, but see that they eat up what is given them. It should be the aim of every farmer to keep his horses in good condition; it takes less feed to keep them in good condition than it does if they get in poor condition. Do not work after sundown—the sweat will not dry overnight and is likely to cause a chill. Horses should be well groomed each morning before going to work; this not only adds to their appearance but also assists in keeping them in good health. Always pay attention to the shoulders when harnessing or grooming; any sores that appear will then be noticed. If collars are kept in good order and fit well there should not be much trouble with sores. Keep the hoofs trimmed. If they become too long they break and split, which often causes lameness. The tail should be pulled each year during May or June; this will give it time to gain proper length so that it will be useful to the animal to protect itself from flies. Pay attention to the mane to see that no knots gather that may interfere with the comfort of the collar. Horses should never be overloaded; with an extra horse in the team you will do more work in a day, have the horses looking better, and less sore shoulders to contend with." Mr. Bruce said that horses which were liable to sore shoulders should be worked with a breastplate. Mr. H. Sanders recommended a tandem team when working eight or more; it was easier on the horses' shoulders and lighter draught. (Secretary, E. Peltz.)

SOUTH AND HILLS DISTRICT.

MILANG (Average annual rainfall, 14.97in.).

July 21st.—Attendance, 13.

UTILISING A SMALL HOLDING TO THE BEST ADVANTAGE.—Paper read by Mr. H. Vivian:—"It is hard to know how to utilise a holding of any acreage to much advantage at the present time, but a small holding in this locality is more suitable for dairying than for any other purpose.

SUBDIVISION.

It will be necessary to subdivide the holding into small paddocks so that a system of rotating grazing may be practised, otherwise the cows will be wandering over the whole areas just picking out the sweetest pastures leaving the other to grow rank. Again there is the advantage in a suitable year of being able to close a paddock for the making of meadow hay which is a valuable standby in lean years. Perhaps with top-dressing and the sowing of suitable grasses it may be possible to cut out the growing of cereals for hay. This point is an important one to the man on a small holding; he has not the land lying idle in bare fallow, which is essential if he is to be assured of a payable cut. It is very necessary that he grow all his fodders. If he has to buy chaff at present price of butterfat there would not be any margin of profit.

FODDER RESERVES.

If one could reserve enough fodder to feed his cows from April to July he should have no trouble in producing sufficient for the rest of the year. We are favoured in this locality with an abundance of good sub-artesian water which can be utilised

cheaply for irrigation purposes. I would grow lucerne for preference. When established it remains for quite a number of years and will produce in abundance if treated correctly. I prefer an engine and centrifugal pump to windmills for irrigation, as one can do the job quicker and there is no inconvenience in waiting for wind when water is wanted urgently. I am convinced that by making the fullest use of this water therein lies our greatest chances of success. One can use lucerne to feed breeding sows between litters, excellent greenfeed for poultry, and any surplus makes good hay. I can grow a ton of lucerne hay cheaper than I can produce a ton of cereal hay, and have the advantage of grazing the lucerne paddocks when the others in cereal would be closed.

Before taking up a holding in this district I inspected a number of blocks along the river. I was greatly impressed by the number of cows these men were carrying on very small holdings; only a few acres of high land, the rest being under irrigation. I feel convinced that if we were to go in for irrigation more extensively we could increase our carrying capacity enormously. A small holder should not fail to explore every avenue where he might add to his income.

PIGS AND POULTRY.

If he is making dairying his main item, pigs should be second consideration. It would pay the small holder better to keep the sows for breeding and sell the piglets at 5 to 10 weeks old than to go in for fattening. By the sowing of a small paddock of barley for greenfeed for winter and spring months and feeding with lucerne during summer, you will only have to buy a few bags of grain during the period when they are feeding their young. For this purpose I would keep Berkshire sows crossed either with Large White or Tamworth. I prefer the Berkshire sows for the reason that they are easier to keep, and either breed should give a pig that will command a ready sale. The keeping of poultry should not be neglected, the weekly sale of eggs will go a long way in keeping the house in groceries. I advocate housing, otherwise they cause a considerable amount of damage by scratching in places where they have no right to be. Eggs are one of the few things that have held their own fairly well during the depression. Vegetables for some time have been cheap; there are none cheaper than your own, therefore the time and labour spent in a vegetable garden will more than compensate for time and trouble. Generally speaking the small holder is in the same position as the wage earner. In the latter case the employer thinks for you, and the small holder must think for himself and exploit every line which shows a profit or saves money that he otherwise would have spent.''

Mr. B. Casley said that the subdividing of the farm was the main item, and that also perhaps different species of grasses could be established. Mr. G. Pannell thought that the pigs mentioned were quite suitable, and stated that they had just had a litter with the similar cross which proved to be the best pigs they had reared on their farm. He also considered meadow hay an excellent standby. (Secretary, L. Yelland.)

GOOD THINGS FROM THE OVEN.

[By GRACE B. ARMSTRONG, A. MARIE SCHRIEBER, and MARY A. MCPHEE, of the University of Illinois, Urbana, U.S.A.]

MISCELLANEOUS QUICK BREADS.

BOSTON BROWN BREAD.

Equipment.

1 steamer	1 measuring cup
2 moulds	1 teaspoon
1 mixing bowl	1 mixing spoon

Materials.

1 c. corn meal	2 t. baking-powder
1 c. graham flour	$\frac{1}{3}$ c. molasses
$\frac{1}{2}$ t. soda	$\frac{3}{4}$ c. sweet milk
$\frac{1}{3}$ c. raisins	$\frac{1}{2}$ t. salt

Amount: 2 small loaves.

Method.

Mix dry ingredients; add molasses and milk. Stir until well mixed; add raisins and turn into moulds or greased baking-powder cans, filling each half full. Place cover on can or tie wax paper over top of can. Steam about 2 hours, or until bread is solid. After removing from kettle, take off lids and brown the bread slightly in moderate oven (350°F.).

One-pound baking-powder tins or coffee cans make good moulds.

GINGERBREAD.

Equipment.

1 mixing bowl
1 teaspoon
1 measuring cup
1 tablespoon
1 flour sifter
1 shallow baking pan

Materials.

2½ c. flour
1 t. soda
½ t. salt
2 t. ginger
1 t. cinnamon
1 c. molasses
1 c. sour milk
4 Tb. melted fat

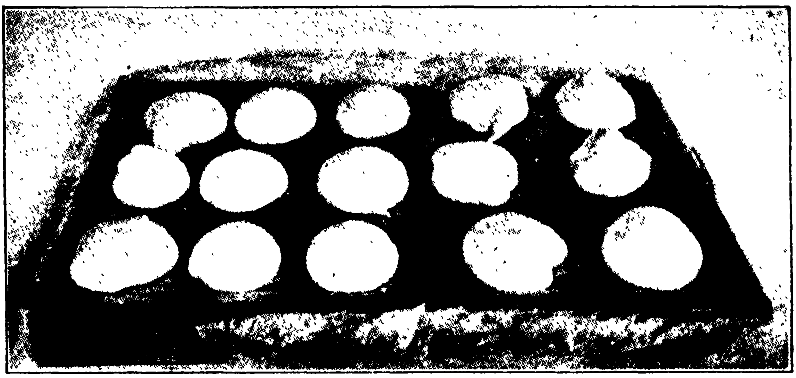

Fig. 6.—Kisses.

Amount: 12 servings.

Mix dry ingredients; put sour milk and molasses in mixing bowl and sift in the dry ingredients, stirring constantly. Add melted fat and beat thoroughly. Turn into shallow greased pan and bake about 25 minutes in moderate oven (350°F.).

Be careful about oven temperature, as any mixture containing molasses burns easily.

NUT BREAD.

Equipment.

1 teaspoon
1 mixing spoon
1 measuring cup
1 mixing bowl
1 flour sifter
1 baking pan

Materials.

1 egg
⅓ c. sugar
½ t. salt
1⅔ c. flour
2 t. baking powder
⅔ c. milk
½ c. chopped nuts

Amount: 12 servings.

Method.

Sift dry ingredients together; add beaten egg combined with milk. Beat well and add nuts. Place in well-greased pan and let rise 30 minutes. Bake 30 minutes in moderate oven (350°F.).

TYPES OF CAKE.

The foundation of all cake products is either the shortened or the unshortened (sponge) cake. There are many variations of these two types of cake. Shortened cakes are those in which the gluten of the flour has been shortened by the incorporation of fat; sponge cakes are those in which egg whites are used as the leavening agent.

SHORTENED CAKES.

INGREDIENTS.

Shortened cakes contain sugar, fat, liquid (usually in the form of milk), eggs, flavourings, flour, and a leavening agent. Nuts and fruit may be added, and various kinds of liquid and sugar may be used.

METHODS OF MIXING.

A shortened cake may be stirred or beaten, or mixed in any other way providing all the ingredients are thoroughly blended. Careless mixing results in a coarse cake; long beating gives a fine but heavy grain, while a small amount of beating makes a light and delicate texture. The *general method* and the *muffin method* are described below. The muffin method is recommended for a simple plain cake; the general method should be used for a richer cake.

GENERAL METHOD.

How.	*Why.*
Sift flour before measuring.	Sifting flour tends to separate the particles. If measured before sifting the extra amount might make the cake too stiff.
Measure and sift dry ingredients together into bowl. (Dry ingredients include such articles as flour, soda or baking-powder, salt, and spices, but do not include sugar, since sugar forms a liquid as soon as it dissolves.)	This distributes dry ingredients evenly through the flour and gives the product a finer texture. If spices are not sifted with flour, they are apt to lump when added to liquid.
Allow fat to stand at room temperature about 5 to 10 minutes before using.	If softened and then slightly creamed before sugar is added, butter or shortening can be creamed with sugar more easily and quickly.
Cream shortening and sugar together, using back of mixing spoon.	Creaming distributes fat more evenly through batter.
Break eggs one at a time into a small bowl.	One stale egg would ruin the product. When broken separately, such a loss is avoided.
Beat eggs well and add to creamed sugar and fat.	Beating eggs allows them to be more easily mixed with other ingredients. Since baking-powder is the leaven used in shortened cakes, it is not necessary to beat whites and yolks separately, although this is done when making a lighter cake.
Sift dry ingredients and add a little to this mixture; stir until smooth. Then add small amounts of liquid and dry ingredients alternately. Stir until smooth. Beat ½ minute. If whites of eggs are beaten separately, fold them in at this time.	Too much beating would develop gluten and make the product tough.

GENERAL METHOD—*continued.*

How.	*Why.*
Pour into greased baking pan; fill only ½ to ⅔ full. Use spatula or spoon to scrape out bowl.	If pans are only partially filled, the cake can rise without overflowing.
When filling pans, gently press batter into the corners, making centre slightly lower than sides.	A more evenly shaped cake results because the cake tends to rise more in the centre than on the sides.
Bake in moderate oven (375°F.). (Follow general directions given below for baking shortened cakes.)	A better shape results if the cake is allowed to rise before a crust is formed over the top. Products with sugar in them tend to burn easily.
After removing from oven, allow cake to stand in pan for 5 or 10 minutes.	After steam has caused the cake to loosen from the pan, it can be removed without injuring its shape.
Remove cake from pan and place it on wire rack or clean white paper to cool, but avoid drafts.	A current of air will dry out the cake.
Keep in ventilated tin box.	A tin box will keep cake from drying out. Ventilation is needed, however, to prevent cake from getting mouldy.

MUFFIN METHOD.

A plain cake may be made by the muffin method, which is a time and labour saver. Sift all dry ingredients together; combine liquid, beaten eggs, and melted fat. Mix the two together. Beat about ½ minute. Egg whites and yolks may be beaten separately and whites added at the last as in the general method.

BAKING SHORTENED CAKES.

The baking of the cake might well be said to be the most important part of the entire process, since so much of the success of the cake depends upon it. Be sure that the oven is the right temperature for the type of cake to be baked (refer to *Oven Temperatures*, page —).

Do not try to bake more than one kind of cake in an oven at the same time, since different types require different treatment. A small cake and a layer cake require a hotter oven than a loaf cake, because they must bake quickly before drying out. A large cake or a loaf cake must bake more slowly so that the heat may penetrate to the centre before too hard a crust is formed on the outside.

Place the cake as near the centre of the oven as possible, as this gives a more even distribution of heat and insures more even rising.

The baking of a cake is divided into four quarters. During the first quarter the cake begins to rise; during the second quarter it continues to rise and begins to brown; during the third quarter it finishes rising and continues to brown; during the fourth quarter it finishes browning and shrinks from the pan. The cake should not be moved while baking, since a jar causes the fragile cell walls to break; the leaven then escapes, and the cake is likely to fall. If it is baking unevenly, it may be moved with least danger during the first and last quarters, but should not be moved just after the crust has begun to form. Open and close the oven door very carefully. If the oven if too hot, lower the heat or place a pan of cold water in the oven. If the cake is browning too fast, put a paper over it, but be careful that the paper does not stick to the cake.

When done, the cake shrinks from the pan; pressed gently on top with a finger, it springs back and leaves no indentation. If baked too slowly, the cake may rise over the sides of the pan and be of a coarse texture. When put in too hot an oven, the cake forms a brown crust on top before it has risen sufficiently; then rising more, it is likely to break through the crust and make a badly-shaped loaf. The oven temperature should be kept as nearly uniform as possible.

Do not open the oven door frequently to look at a cake. Be sure of the oven temperature before putting the cake in, then open the door only once or twice during the entire baking.

Cakes containing such substances as dried fruits, molasses, or chocolate tend to burn quickly, and must be baked at a slightly lower temperature than a plain cake.

SUCCESS OR FAILURE IN CAKE MAKING.

Recognition of the causes of success or failure in cake making gives one assurance, and makes more uniform results possible. A few of the general causes of success or failure are given below. Consider the finished product, judge it, and let your observations be a guide to greater success.

SUCCESS DEPENDS UPON:—

A well-proportioned recipe.
The use of fresh and well-flavoured ingredients.
Careful measuring and mixing of ingredients.
Careful baking with right oven temperature.

FAILURES AND THEIR CAUSES:—

A heavy product or the falling of a cake may be due to—

Too slow an oven.
Too much sugar or fat, or both.
Too little flour.
Moving the cake in the oven or jarring it before it is set.

A coarse-grained product may be due to—

Too slow an oven.
Too much leaven.
Careless mixing of ingredients.

"Bready" appearance and cracks on top may be due to—

Too much flour.
Too hot an oven at first.

Uneven rising of the product may be due to—

Cake being placed near one side of the oven.
Oven being too hot on one side.
Too much flour.

Rough edges may be due to—

Too much sugar.
Too much shortening.
Too little flour.

PLAIN LOAF CAKE.

Equipment.

2 mixing bowls	1 teaspoon
1 small bowl	1 flour sifter
1 measuring cup	1 egg beater
1 mixing spoon	1 loaf pan

Materials.

⅓ c. butter	1½ c. flour
⅔ c. sugar	¼ t. salt
2 eggs	2 t. baking-powder
½ c. milk	

Amount: 1 loaf cake 3in. x 3½in. x 8½in.

Method.

Use either general or muffin method for mixing shortened cakes. Bake in moderate oven (350°F.) 45 minute to 1 hour.

LAYER CAKE.

Equipment.

Same as above except layer cake pans instead of loaf cake pan.

Materials.

Same as for plain cake.

Amount: 3 round layers 9in. in diameter.

Method.

Use either general or muffin method for mixing shortened cakes. Bake in moderate oven (375°F.) 25 to 35 minutes.

STANDARD CAKE.

(1-2-3-4 Cake.)

Equipment.

Same as for layer cake.

Method.

1 c. butter
2 c. sugar
1 c. milk
4 eggs
1 t. flavouring
3 c. flour
4 t. baking-powder

Amount: 2 loaf cakes 3in. x 3½in. x 8½in., or 4 round layers 9in. in diameter.

Method.

Use general method described for mixing cake. Bake loaf cake at 350°F. and layer cake at 375°F.

JELLY ROLL.

Equipment.

1 mixing bowl
1 small bowl
1 mixing spoon
1 tablespoon
1 teaspoon
1 flour sifter
1 measuring cup
1 egg beater
Oiled paper or clean wrapping paper
1 shallow dripping pan

Materials.

3 eggs
1 c. sugar
½ Tb. milk
1 c. flour
1 t. baking-powder
¼ t. salt
1 Tb. melted butter
Jelly stirred or mixed thoroughly

Amount: 1 jelly roll 12in. x 6½in.

This proportion of eggs to flour makes a tough product which can be rolled without breaking. A larger proportion of shortening and liquid would make the product too tender to roll.

Method.

How.	*Why.*
Line bottom of dripping pan with paper. Grease paper and sides of pan.	Paper makes it possible to remove a thin cake from pan without breaking edges of cake.

METHOD—*continued.*

How.	*Why.*
Beat eggs until light. Gradually add sugar, then milk.	Eggs serve as part of liquid to dissolve sugar.
Sift and add dry ingredients. Put in melted butter.	Butter blends better with other ingredients if added last.
Spread mixture evenly over bottom of pan. A fairly large pan should be used so that cake will be only about ¾in. thick when baked.	A thicker cake is likely to crack when rolled, and a thinner cake dries out before it is sufficiently baked.
Bake 15 to 20 minutes in slow oven (300°F.). Meanwhile stir jelly to spreading consistency.	Too hot an oven makes the cake hard and crusty. Over-baking dries it out.
Take cake from oven, loosen edges, reverse pan, and allow cake to fall out on a paper sprinkled with powdered sugar.	The moist underside of the cake is thus placed uppermost, while the seared surface is at the bottom and is covered with sugar. Sugar helps to make the roll stick together and also makes an attractive finish.
Quickly remove paper which has lined pan and now adheres to cake.	Unless removed quickly, paper is likely to stick to cake.
Cut off a thin strip of cake from sides and ends.	This crusty part would crack if rolled.
Spread a moderate amount of stirred jelly or jam over cake.	If too much jelly is used, it will soak in and make the product soggy.
Everything should be ready for rolling when cake leaves the oven, for this entire process must be done quickly.	If cake is allowed to cool, it will dry out somewhat and tend to crack in rolling.
Roll up cake quickly and fasten paper about it. Be careful not to press or roll too tightly. When cooled slightly, remove paper.	Paper will keep the roll in shape until it has cooled, when it will retain its shape without being held in place.

NUT CAKE.

Prepare plain cake recipe (see page —), using ¼ cup of butter and ½ cup of walnut or hickory nut meats ground or chopped fine instead of ⅓ cur butter. The nuts should be added last. If they are in large pieces, it it necessary to flour them and to use 1 tablespoon more of fat.

GOLDEN SPICE CAKE.

Equipment

1 mixing bowl	1 mixing spoon
1 measuring cup	1 egg beater
1 teaspoon	1 grater
1 flour sifter	1 loaf pan

Materials.

½ c. shortening	½ c. brown sugar
½ c. molasses	½ c. milk
1 egg	4 egg yolks
2¼ c. flour	1 t. baking powder
½ t. soda	½ t. cloves
1 t. cinnamon	½ t. grate lemon rind

Amount: 1 loaf cake 3in. x 3½in. x 8½in.

Use general method for mixing cake (see page —). Bake in moderate oven (350°F.) about 45 minutes.

Apple Sauce Cake.

Equipment.

Same as for golden spice cake except for addition of sieve.

Materials.

1 c. sugar	2½ c. flour
½ c. shortening	1 t. soda
1 c. apple sauce (unsweetened and consistency to pour)	1 t. cinnamon
	¼ t. cloves
	¼ t. nutmeg
	1 c. raisins.

Amount: 1 loaf cake 8½in. x 3½in. x 3in.

Method.

Cook apples until very soft; then put them through a sieve Do not sweeten. The sauce must be in a smooth, fine condition or a coarse-grained cake will result. Clean raisins. Use either general or muffin method of mixing (see page). Apple sauce is added in place of other liquid. Bake in slow oven (325°F.) about an hour. Keep in a covered tin box. This cake, while inexpensive, has the qualities of very rich fruit cake, and will keep moist for some time.

Dark Fruit Cake.

Equipment.

1 mixing bowl	1 mixing spoon
1 measuring cup	1 egg beater
1 teaspoon	1 knife or food chopper
1 flour sifter	1 loaf pan

Materials.

½ c. butter	½ t. allspice
¾ c. brown sugar	½ t. mace
½ c. molasses	¼ t. cloves
½ c. milk	½ t. lemon extract
2 eggs	¾ c. raisins
2 c. flour	¾ c. currants
½ t. soda	½ c. citron thinly sliced and cut in strips
1 t. cinnamon	

Amount: 1 loaf cake 8½in. x 3½in. x 3in.

Method.

Clean dried fruit. Chop raisins with knife or put them through a coarse food chopper. Cut citron rather fine. Reserve about 3 tablespoons of flour with which to flour the fruit.

Prepare according to general directions (see page 34). Flour the fruit and add last, stirring the mixture well to be sure that the fruit is well distributed. Put in a deep pan and bake about 1¼ hours in slow oven (300° F.). Be sure the cake is thoroughly done. The more fruit used, the longer the time required for baking. Slow baking avoids burning, and allows the fruit flavour to penetrate the entire cake. A cake of this kind will keep a long time, and has a better flavour a few days after baking. Since it is very rich, small servings should be given.

Devil's Food Cake.

Equipment.

1 double boiler	1 egg beater
1 measuring cup	1 mixing bowl
1 teaspoon	1 or 2 loaf pans
1 flour sifter	

Materials.

(1) ¼ cake bitter chocolate
1 c. sugar
¾ c. sweet milk

(2) 1 c. sugar
⅔ c. butter
¾ c. sour milk (clabbered)
1 t. vanilla
3 eggs
1 t. salt
1 t. soda
2 t. baking-powder
2⅔ c. flour

Amount: 1 loaf cake 10in. x 6½in. x 2in., or 2 loaves 8½in. x 3½in. x 3in.

Method.

How.	*Why.*
Melt chocolate in top of double boiler or in dish placed over hot water.	Chocolate should melt slowly so that it will have a smooth consistency and will blend well with other ingredients.
Remove from over hot water and add sugar to melted chocolate. Stir well.	If chocolate remains over heat after melting, it becomes thick as a result of the cooking of the starch in the chocolate and the separation of fat from other substances and does not mix well with other ingredients.
Add milk slowly, stirring constantly.	Milk dissolves sugar and makes a liquid which can be beaten into cake batter easily.
Allow to stand until Part 2 is prepared. Prepare Part 2 according to general method for mixing cake (see page).	
When Part 2 is thoroughly mixed, add Part 1 and beat only until the 2 batters are well blended.	An even colour and texture result from thorough mixing.
Bake as a loaf cake in moderate oven (350°F.) for 40 minutes to 1 hour, depending on shape and size of loaf.	If cake is thick, it will require a longer time for baking.

If cocoa is used instead of chocolate, it may be sifted with the flour or mixed with the sugar, the sugar and milk of Part 1 may be added to Part 2, and the amount of flour called for reduced by ½ cup. Three tablespoons of cocoa is equivalent to 1 square of chocolate.

(To be continued.)

[Next month's issue will deal with Cookies.]

KYBYBOLITE (Average annual rainfall, 22in.).
May 8th.—Attendance, 19.

DOMESTIC ECONOMY.—Paper contributed by Mrs. P. Laurie:—"In these days of lessened incomes we are obliged to economise very considerably in the work and management of the home, and in that way do our part in helping our men folk to meet the needs of the present time. I propose to give some suggestions and also a few recipes that are most suitable for the country housekeeper.

Houshold Soap.—At the present time and for some time past tallow has been very cheap, so there is an abundance of it which can be made into soap with very little trouble. These two recipes are reliable. The first is excellent for household and laundry work and is not hard on the hands:—½ kerosene tin rainwater, 5lbs. fat, ¾lb. resin, boil for about 10 minutes. Lift off fire and add 1 tin caustic soda very gradually, 1 handful of borax, ½ cup cloudy ammonia. Boil all togther steadily for 2½ hours. The second one is a little more expensive and slightly more trouble:—6½lbs. fat

—free from salt—2galls. water (except 2 pints), ½lb. resin, 2 tablespoons each of borax, rock ammonia, and olive oil, 1 large pkt. lux. Mix and boil until all are dissolved, then add 1lb. caustic soda dissolved in 2 pints of water; mix slowly. Boil all for 2 hours or more; take off fire and add ½ cup each of kerosene and petrol. In the other recipe I used the same amount of kerosene and petrol after taken off fire. It is necessary to leave it for several weeks before cutting it up into small pieces; this prevents it from shrinking.

Porridge made from Wheat.—Wheat is only a few shillings a bag now, and a grain-crusher can be bought for about 15s. Where there are growing children in households who are fond of porridge the little grister will pay for itself in a very short time. See that the wheat is free from husks, then put it through the grinder. I have had mine for about three years and always have it in use right through the winter, as we use a lot of wholemeal for biscuits and other cooking as well as for porridge.

Preserving Eggs.—Eggs are best kept in a basket. If held up to the light an egg if fresh should be clear, if thick it is stale. Eggs are most plentiful and cheapest in the late spring. They may be preserved for future use by rendering them airtight to prevent decomposition. The simplest treatment is to coat them thoroughly with lard or mutton fat, then pack them in a wooden box well perforated with holes and standing off the ground a few inches to allow for the circulation of a good current of air. Another way is to pack them in salt, narrow ends downwards, after having greased them.

To Dry Fruit.—*Prunes*: To 4galls of water add 1 teaspoon of caustic soda and bring the water to the boil. Have the plums ready in a sugar bag, hold the mouth of the bag in one hand and immerse the bag with the plums in the boiling water while you count 10—not longer or the plums will burst. Then turn the fruit out on trays in the sun until dry, which will take about a fortnight. *Apples*: Peel, core, and slice the apples. Have a large bowl of salted water ready (not too salt) and put them in as soon as they are ready. This is to keep them a nice colour, then drain for a little while, and turn on trays in the sun until dry. *Apricots, Peaches, Pears, &c.*, can be done by halving them and taking out stones. A good way to dry all fruit is to have a long rather narrow wooden frame and tack close-mesh wire-netting to it. Turn the fruit on to this and place it on trestles in the sun. If the weather is good, put it out in the morning and always bring in at night. The wire-netting allows the air to get underneath and so dry the fruit quicker and more thoroughly. When storing away, put in new unbleached calico bags—ones that have not been washed—sprinkling a little sulphur amongst the fruit; this will keep all weevils away.

To Clarify Fat.—This is an excellent way in which one can always be sure of good soft mutton fat. Boil the fat with water until all the water has boiled out of it, then turn it out. This will keep indefinitely and will not go rancid.

A Permanent Blacklead.—Try mixing a cake of blacklead with an equal weight of bluestone crystals. Mix to a paste with cold water and apply to the stove with a brush. The heat will bake the surface to enamel brilliance, and with an occasional brush up the treatment should last for months.

A Substitute for Starch.—If you run out of starch, ordinary flour will do very well made in the same way as starch and with a small lump of butter added to it.

To Mend a Lace Curtain.—If there is a hole in a lace curtain or any net or thin curtain, match the pattern with some of the scraps of the materials and just stick it over the hole, ironing smoothly with starch. It will make a much better job than mending it, as the patch will not be seen at all.

Floor Polish.—This is a very good polish for either furniture or floors and is not too slippery, and is reliable for restoring a polished surface—1oz. shredded beeswax, ½oz. each shredded white wax and shredded soap, ½pint each turpentine and boiling water. Melt the waxes in a tin, add the soap dissolved in boiling water, then the turps (off the fire). Stir occasionally until the mixture is a white cream, bottle in a wide necked bottle and keep corked.

French Polish.—2ozs. shellac, 1oz. gum mastic, 1 pint methylated spirits. Crush the gums, sift through muslin, dissolve slowly over gentle heat, add the spirit, bottle and cork at once. Put a piece of cotton wool saturated with this polish on linen, doubling it over to form a pad, and then polish, every movement being in a circular direction. Much energy, time, and patience are necessary to obtain a pleasing result.

To Remove Stains.—Ink may be removed by gently rubbing in milk that has been boiled but is somewhat cooled, changing the milk as soon as it becomes discoloured. Wet ink on white material should be rubbed with a piece of lemon as soon as the ink is soaked up, rinse quickly and repeat if necessary. *Wine and Fruit Stains*: While wet sprinkle salt on the spot, pouring boiling water through, or soak the stain for a few minutes in boiled milk. *Tea and Coffee Stains*: These should be attended to while wet. Spread the stained part over a basin and pour boiling water through until marks disappear. *Iron Mould*: Pour boiling water through yellow mark, lay on it a pinch of salts of lemon, then pour boiling water through again. Repeat this as an old mark is usually very obstinate.

Washing the Floor.—There is a certain amount of kerosene in the composition of linoleum, so when washing the floor, be sure to use a little kerosene in the water to preserve the linoleum and considerably lengthen its life.

For Scouring Pots, &c.—Melt down a bar of home-made soap and stir in as many sifted ashes as it will take, put into tins. This is very good for cleaning aluminium ware.

The Care of Beds.—The Mattress: In this climate wire mattresses are apt to rust in winter; it is a good plan to paint them with aluminium paint to protect the bedding from rust. Then if you make a case of unbleached calico—like a big pillow case with tapes at one end and just slip it over the mattress—it will prolong its life considerably. Have a covering over the pillows also in addition to the pillow case to save the ticking. Very nice coverings for children's beds can be made from any scraps of old blanket or woollen material of any kind, spread out and tacked on to thin calico, then covered with a suitably coloured washing cretonne or chintz. They are beautifully snug and warm and take the place of about two blankets. *To Wash Blankets*: Half a bar soap cut finely. Pour over it 1 pint of boiling water, put on the fire and stir until a thick paste. Mix into it 2 tablespoons of ammonia. Have ready a copper of tepid water softened with 1 tablespoon of borax, stir in the mixture, then put in the blankets. Let soak 1 hour, turning them over frequently, and be sure to keep the water warm, not hot, a few sticks under the copper will do this. Then run through the wringer and rinse in clear tepid water; no rubbing. (Secretary, Mrs. Kekwick.)

June 26th.—Attendance, 17.

POULTRY.—Paper read by Mrs. C. Hann:—"We are not in a favourable situation so far as markets are concerned, to make poultry farming by itself a payable proposition, being in a cold district and a long way from the market. It is my intention to deal with this subject mainly as a sideline on the farm. Most farms try to produce eggs without too many of the modern conveniences. When starting with poultry, select pure bred foundation stock and always keep the breed pure. Do not cross different breeds. Most people have a preference for a certain breed, and the person with a preference for a certain breed will get more out of those fowls than from a breed they do not like. Any of the recognised laying strains will give good results provided they get the right treatment. Having chosen the breed and strain of fowls the next important point to consider is the number you intend to keep. Do not keep 200 fowls if you only have accommodation and feed for 100. Fifty good fowls, well looked after, will give more eggs than 200 badly housed and half fed. On most farms fowls have free range and pick up quite a lot of their own feed. The house should be built in a well sheltered position facing the east, be well ventilated, and free from draughts. For 50 fowls a house 12ft. x 12ft. x 6ft. high or higher is necessary. Always give plenty of room on the perches and always have all perches on the same level, otherwise the fowls will always crowd the higher perches. It is essential to have some small yards and houses in which to keep breeding fowls during the breeding season, to keep cockerels separate from the hens and to use for fattening any others for market. See that everything is kept clean; houses, water and feed troughs should be cleaned and disinfected at least once a week. All nests should be kept clean, and on no account should the fowls be allowed to roost in the nests. The most troublesome pests are tick, lice, and red mite. See that there is a good dust bath available for the fowls. This can be kept dry in a corner of the house. The bath should consist of wood ashes with a handful or two of lime in it. If this is provided the fowls will disinfect themselves. As most of these pests live in the woodwork and crevices of the house and perches it is necessary to attack them there. To destroy these pests it is necessary to saturate occasionally all woodwork inside the house and nests with kerosene or sump oil. Another important item is selecting the breeding pen. Remember that the cockerel is very important, he represents practically half the breeding pen. Too many farms allow a half dozen cockerels of their own breeding to run with their flock of hens and pullets and set the eggs from their bulk collection. By this method they are soon bound to deteriorate instead of improve their flock. Having selected or bought a good cockerel select hens for the breeding pen carefully. Select second year or other hens that are active and true to the type you are breeding—usually the first off the perch in the morning and the last on the perch at night; the pen that is always scratching and looking for work is the one that produces the eggs. Never breed from pullets if you have hens available, the chicks are usually weak and hard to rear, and do not mature as quickly as from older hens. It does not pay to keep hens for egg production after their second season. Always try and hatch chickens so that the pullets will commence to lay about March or April when the older hens are going into moult. Allow about five months for light breeds—Leghorns, Minorcas, &c.—and six to seven months for heavy breeds such as Orpingtons, &c. Get rid of the cockerels as soon as they are fit to go on the table; it does not pay to have them eating the feed from the hens. It usually pays to separate the cockerels from the pullets as soon as you can distinguish the sex. Force the cockerels along to get rid of them early. ***Feeding:***

Fowls should be fed twice a day in winter when there is plenty of greenfeed and they have free range, but if they are penned it is essential that they get greenfeed at midday. The flock on range should have greens during summer to keep them healthy. Fowls should be given mash in the mornings, consisting of bran 2 parts and pollard 1 part, usually the bran is scalded with hot water or mixed with separated milk and then dried down with the pollard so that it is crumbly and fed in troughs. A little meat meal should be added if there is no other meat available for the fowls. The right feed should consist of grain, preferably wheat, or a mixture of grains thrown on the scratching litter. Fowls, particularly if penned, must have exercise, and the surest way of giving them this is to have about 6in. of straw in the yard on which to throw the grain. I can get twice as many and better eggs from my breeding pens if I keep them well supplied with scratching litter. A recent authentic Government test also proved that feeding mash, greenfeed, and grain against grain increased the egg yield by from 50 to 80 per cent., in some cases more. In hatching, the incubator and broody hen are both used; the hen is certainly the least trouble, but it is usually late in the season before you can get your number of chicks hatched and then the trouble occurs that there are not any eggs when the hens go into the moult. Turkeys usually set fairly early and make good mothers. Chicks should be kept warm, given plenty of cracked grain, hulled oats, bran, or bread crumbs, with greenfeed chopped very fine, also provide shallow clean water tins and keep them filled. A few "don'ts":—

Don't expect the maximum if you only supply the minimum.
Don't expect fowls to keep warm during winter roosting in a gum tree.
Don't forget to gather all eggs regularly.
Don't forget, infertile eggs will keep longer than fertile.
Don't forget to keep drinking water clean and cool and in the shade.
Don't bother with weakly chicks, weak chicks never make good hens.
Don't forget it pays to produce large eggs of good quality.
Don't try and run 100 hens if you are only going to buy enough for 50.
Don't be satisfied with anything but the best. (Secretary, Mrs. Kekwick.)

MANGALO (Average annual rainfall, 14in. to 15in.).
July 12th.—Attendance, 15.

Mrs. R. Crittenden read a paper, "Care of Baby."

HOUSEHOLD HINTS.—The following were supplied:—(Mrs. A. J. Hissey) When making bread in winter it will rise more quickly if placed in an open fireplace, which has contained a fire the night before. If when washing greasy pans they are first wiped out with a piece of newspaper, they are more easily washed and it will prevent the dishcloth and water from becoming greasy. When sewing, if any turnings are pressed down with a warm iron, they remain flat and are easier to handle. Eucalyptus will remove grease from any article without damaging colour or fabric. (Mrs. H. Klingberg)—When mending stockings, always run the hole around the edge first; this makes the edges flat and draws the hole together, making it easier to darn. Fried eggs will not break or stick to the pan if a little flour is added to the frying fat. A teaspoonful of ammonia added to a bowl of warm water removes fruit stains from fingers. To clean the copper, put the dirtiest soapsuds in it after the day's washing and leave for two days, then empty and the copper will be shiny. Alum can be used very effectively for mending broken china, glassware, &c. Melt a little in an old iron spoon, apply it to the broken parts and leave until it hardens. A small piece of alum added to vinegar when pickling helps to make pickles nice and crisp. (Mrs. P. Cleave)—Oil and eucalyptus applied instantly to a burn will prevent a blister and relieve the pain. Eucalyptus if immediately applied to a cut or scratch will cleanse the wound and stop the bleeding. Before washing new cotton, allow the material to soak in cold water in which a little Epsom salts or salt has been added. If before washing new sheets or men's denims, they are allowed to soak in cold water into which common salt is added they will be soft and easy to wash. (Mrs. A. E. Lathlean)—When the top thread of the sewing machine constantly breaks, reverse the needle. When tea has been spilt on a cloth, sprinkle a little sugar on the stain and thus prevent the stain from setting. Paint can be removed from clothes with a solution of ammonia and turpentine. (Miss J. James)—A teaspoon of lemon juice in a small cup of black coffee is almost certain to relieve a bilious headache. Mildew may be removed from leather goods by rubbing first with vaseline then a soft cloth. Soak cabbage or cauliflower in water with a little vinegar and it will remove the insects quicker than if salt is used. (Mrs. T. Coles)—If the teapot is changed every few months the tea will taste fresher and nicer. When making a sponge, put the baking dish with the eggs and sugar in it into a dish of boiling water. They will beat up in less than half the time. When dusting, put a little kerosene on the duster. It takes up the dust much better. Before washing greasy dishes, scrape them thoroughly with an old bendy knife. The task seems much easier then. If carpets or mats look dirty, rub cloudy ammonia over them and it will brighten them. Before knitting socks or infants clothes shrink the wool by soaking it in some water. After unpicking a knitted article wind the wool into skeins around two chairs and soak it in some warm soapy water. When dry the wool will be like new wool. (Secretary, Mrs. F. Cole.)

McLAREN FLAT.

June 7th.—Attendance, 19.

RECIPES FOR AFTERNOON DAINTIES.—*Three Minute Sponge* (Mrs. S. Elliott): 2ozs. butter, ¾ cup sugar, 1 cup plain flour, 2 level teaspoons cream tartar, 1 teaspoon carb. soda, about 4 tablespoons milk, 3 eggs. Warm butter slightly, put all together in a basin, and beat 3 minutes only. Bake 10 to 15 minutes only in moderate oven. *Orange Cream Cakes*: 2ozs. butter, 4ozs. sugar, 2 eggs, 3 tablespoons milk, 8ozs. flour, 2 oranges, whipped cream. Cream butter and sugar and eggs, well beaten, then milk and flour and grated rind and juice of lemon. Mix well and bake in containers. Decorate with whipped cream and orange slices. *Sultana Olives* (Mrs. J. E. Bruce): Chop some olives and gherkins very fine and mix with cream cheese, season to taste, place 1 teaspoonful on a buttered sultana cracker biscuit. Garnish with small pieces of gherkins and stuffed olives. *Anchovy Cheese*: Butter a small cheese biscuit, place a ring of hard white boiled egg upon it; in centre of ring place a small curled anchovy. Sprinkle with a little pepper. Garnish with chopped egg yolk. *Sponge Lilies* (Mrs. Sigston): ¼lb. each sugar and flour, 2 eggs, ½ teaspoon baking powder. Mix as for sponge, drop from a dessertspoon on to buttered tray. When lightly brown and while hot, roll into shape like a lily, fill with whipped cream. *Chocolate Dainties* (Mrs. Bick Elliott): Beat 4ozs. butter and 4ozs. sugar to a cream. Add 2 well beaten eggs, sift in 4ozs. S.R. flour, 2ozs. cocoa, add 2 tablespoons milk, bake in patties in a moderate oven 10 to 15 minutes. When cool cut the centre and fill with cream filling flavoured with vanilla, put top on again and sprinkle with icing sugar. *Cream Puffs* (Mrs. Sigston): 2ozs. each butter and flour, 2 eggs, 5 tablespoons water. Bring water and butter to boil in saucepan, stir flour in gradually, cook for about 5 minutes, stirring all the time into a smooth paste, allow to cool, then break in eggs, one at a time, and beat well. Drop in small spoonfuls on greased tray. *Cream Cakes*: 2ozs. butter, 4ozs. sugar, 2 eggs, 4ozs. S.R. flour, flavouring to taste. Bake in moderate oven for 10 minutes. *Chocolate Dominoes*: Make sponge mixture by beating 2ozs. butter, 3ozs. sugar to cream, add 2 eggs, well beaten, 4ozs. flour, ½ teaspoon soda, 1 teaspoon cream tartar (sift flour, &c., 3 times), beat well together and pour into square tin and bake about 20 minutes. ● FULL MOON.

chocolate icing, and when set cut into domino shape, as near as possible, and put dots on with royal icing. Royal Icing: 1 tablespoon icing sugar, lemon juice, and beat with a little white of egg until stiff. *Naugat Seeaps* (Mrs. H. G. Air): Mix ½ cup rolled oats, ¾ cup S.R. flour, and 1 cup sugar. Dissolve 1 tablespoon honey or golden syrup in 2 tablespoons boiling water and stir in dry ingredients. Lastly stir in 1 teaspoon carb. soda in 4ozs. butter (melted). Mix well and allow to stand for a while to let the oats swell. Drop teaspoonful on greased tray. Keep far apart and when cooked leave on tray until cool. *Piquant Dainties*: Boil 2 eggs until very hard, shell and cut into halves lengthways. Take out yolk and eggs and mix in a basin with a small teaspoon each of tomato sauce and Worcester sauce. Pepper and salt to taste. Mix to a paste, cut white of eggs lengthways, to make boat shape pieces. Place on savoury dainty biscuits, or any other biscuits that will take the boat shape eggs, fill with the yolk mixture. Make a hole in centre with a small piece of lettuce, nice and crisp, to make it look like a sail on a boat. Garnish with small pieces of pimento. *Cream Puffs* (Miss R. Elliott): 1 cup hot water, ½ cup butter, boil together, and while boiling stir in one cupful of dry flour. Take from the stove and stir to a smooth paste. After this cools, stir in 3 eggs not beaten, stir 5 minutes. Drop in tablespoons in a buttered tin, and bake in a quick oven for 25 minutes. Do not let them touch each other, and do not open the oven door more than is absolutely necessary. *Mock Cream Filling* (Miss R. Elliott): Boil 1 cup milk, thicken with 1 tablespoon cornflour, and allow to cool. Beat 2ozs. each butter and icing sugar to a cream, add first mixture a little at a time, until used up, beating well all the time, flavour with vanilla. (Secretary, Miss S. Nicolle.)

All communications to be addressed:

"The Editor, Journal of Agriculture, Education Building, Adelaide."

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences.

District Conferences will be held as follows:—

Fruit (Non-irrigated Districts), at Balhannah, Tuesday, November 6th, C. G. Grasby (Secretary).

The Conference will commence at 10.30. Members of Branches are invited to submit papers and questions for the agenda.

Agricultural Shows.

We have been advised by Secretaries of Agricultural Show Societies that their shows will be held as follows:—

Murray Bridge, Thursday, October 25th.

Woodside, Saturday, November 3rd.

Linseed Meal for Horses.

Mr. C. McKenna, B.V.Sc., Stock and Brands Department, advised delegates from the Lameroo Branch at the Pinnaroo Line Bureau Conference that for a draught stallion weighing 15cwt. which is travelling during the season, the following daily ration is recommended:—Good quality oaten chaff, 20lbs.; oats, 9lbs.; bran, 4lbs.; linseed meal, 3lbs. For working farm horses of an average weight of 1,200lbs. for light draughts to 1,400lbs. for draughts, suitable rations would be:—

(*a*) For medium work, *e.g.*, ploughing: Good quality wheaten or oaten chaff, 17-19lbs.; oats, 7lbs.; bran, 3lbs.; linseed meal, 1lb.

(*b*) For heavy work, *e.g.*, binder: Good quality wheaten or oaten chaff, 17-19lbs.; oats, 11lbs.; bran, 4lbs.; linseed meal, 1lb.

Lower North Pruning Competitions.

The report of the Lower North Pruning Competitions—Langdon Parson's trophy—which appeared on page 103 of the August issue records the name of A. Hentschke with 530½ points—this should be A. Andriske. C. A. Hoffman who scored 543 points was omitted and is the next to highest competitor.

Pasture Competitions.

Successful livestock management is very largely dependent upon the provision of satisfactory pastures, and in order to draw attention to the best pasture types and the methods by which such pastures were brought to the maximum degree of production, pasture competitions for various districts were commenced by the South Australian Committee of the Australian Dairy Council in 1932.

This season it has been decided to hold the competitions in four (4) districts, namely, Hills (over 22in. rainfall), South-East (over 22in. rainfall), irrigated areas and all districts with under 22in. annual rainfall.

Pasture entries must not be less than five acres in area, with the exception of the irrigated areas, and in this case the area must be not less than two acres. In judging, points will be allowed according to the area of pasture submitted.

Prizes are offered in each district, consisting of trophies to the value of £3 3s., £2 2s., and £1 1s., together with Certificates. A fee of 1s. will be charged for each entry.

Competitors will be asked to state clearly in their applications—(*a*) location of the pastures, (*b*) area of the pastures.

Entries are due with the Secretary of the Committee not later than Thursday, November 1st, 1934, and are restricted to dairymen milking at least seven (7) cows. Forms may be obtained from the Secretary, South Australian Committee of the Australian Dairy Council, office of the Minister of Agriculture, Flinders Street, Adelaide.

The Relative Food Value of Crushed Wheat and Oats when Fed with Cocky Chaff?

Replying to this question which was submitted at the Conference of Pinnaroo Line Branches of the Agricultural Bureau, Mr. W. J. Spafford, Deputy Director of Agriculture, said to compare foodstuffs of similar kind, such as grains, when used for fattening or maintenance purposes, is fairly easy, because the Starch Equivalents of the materials are strictly comparable

When the production of (*a*) milk, (*b*) eggs, (*c*) growth in young animals, or (*d*) fast or heavy work, are concerned, however, it is a much more difficult proposition, because the amount of digestible crude protein present and its relation to the digestible fat, carbohydrates and fibre must be considered as well as the Starch Equivalent, and a comparison of foodstuffs for any of these purposes is a rather complicated calculation. When arriving at the nutritive value of foodstuffs so that they can be compared it is usual to use the figures showing the digestible nutrients to calculate the *Starch Equivalents* and the *Nutrient Ratio* and to compare the foodstuffs on the figures obtained. A foodstuff with a high Starch Equivalent and a wide Nutrient Ratio, *i.e.*, little digestible crude protein and a lot of digestible carbohydrates, will be good for fattening purposes, whilst one with a low Starch Equivalent and a narrow Nutrient Ratio, *i.e.*, a lot of protein and relatively little of carbohydrates will be a good milk producer, and a general-purpose feed is one containing a fairly high Starch Equivalent and a fairly narrow Nutrient Ratio.

Plump Wheat (63½lbs. per bushel) has a Starch Equivalent of 76 per cent. and a Nutrient Ratio of 1 to 10.4; Shrivelled Wheat (51¼lbs. per bushel) has a Starch Equivalent of 72¼ per cent. and a Nutrient Ratio of 1 to 8.3, and Algerian Oats have a Starch Equivalent of 59 per cent. and a Nutrient Ratio of 1 to 7.8.

As Cocky chaff is a relatively poor foodstuff for farm animals, added concentrates will need to supply most of the nutrient the livestock are to receive, and on the figures quoted it will be seen that crushed plump wheat will be the best addition for fattening animals, shrivelled wheat easily the best general-purpose concentrate, and oats a slightly better milk producer.

Gold Medal Competition for Butterfat Production.

Seven years ago the United Dairy Cattle Breeders' Association of South Australia inaugurated among its members a butterfat production competition, the figures for which were to be based on the results of official testing, and the computations to be made by officers of the Department of Agriculture.

A special set of rules was drawn up by the Association. Special handicaps were agreed to for the various age cows, and certain concessions permitted in respect of cows which, owing to illness or other eventualities, would be unable to produce to the maximum of their capacity. These rules have undergone slight changes during the seven-year period, and handicaps have on occasions been altered to adjust, according to the Association's opinion, the normal disparity of production between the younger and the older cows.

The rules for the year 1933-34 were as follows:—

1. At least six cows per herd to be entered for competition.

2. In herds of more than six cows owners were permitted to withhold from competition 25 per cent. of their number, but not more than 25 per cent., and with the proviso mentioned in Rule 1.

3. Handicaps were:—

	lbs. Butterfat.
For junior 2-year-old cows	120
For senior 2-year-old cows	100
For junior 3-year-old cows	80
For senior 3-year-old cows	60
For junior 4-year-old cows	40
For senior 4-year-old cows	20
For mature cows	Nil

The winner of the competition in the year just closed is one whose name has headed the list as many as four previous occasions, and is the well-known Friesian breeder, Mr. C. J. Morris, of Monteith. Mr. Morris to be congratulated on again winning the much-coveted place of pride and distinction, and for adding still another gold medal to his valuable collection of trophies.

Appended are the winners for the seven years:—

	lbs. Butterfat.
1927-28—Mr. C. J. Morris, Monteith	556.58
1928-29—Mr. J. A. J. Pfitzner, Hampden	456.81
1929-30—Mr. C. J. Morris, Monteith	496.69
1930-31—Mr. C. J. Morris, Monteith	465.21
1931-32—Mr. C. J. Morris, Monteith	560.94
1932-33—Mr. C. E. Verco, Mount Compass	563.47
1933-34—Mr. C. J. Morris, Monteith	552.48

Mottle-Leaf of Citrus.

The Secretary of the Beetaloo Valley Branch of the Agricultural Bureau has been advised by the Deputy Chief Horticultural Instructor (Mr. A. G. Strickland, M.Agr.Sc.) that mottle-leaf occurs in all countries where citrus is grown, but owing to the many different factors which have been shown to contribute to the condition, the questions of cause and control cannot be answered in a general statement.

In every instance the trouble is due to faulty nutrition, but the respect in which nutrition is faulty need not necessarily be the same in all cases, and, furthermore, the factors which bring about unbalanced feeding of the tree may also vary. Among the many possible explanations of mottle-leaf in citrus are:—Insufficient nitrogen, excessive nitrogen, lack of humus, deficiencies of certain elements (such as zinc), or the presence of toxic minerals (such as Lithium or Boron) in soil or irrigation water. In respect to the last-mentioned explanation, one serious outbreak of mottle-leaf in California was traced to soil contamination with drainage from a fruit-washing plant using the borax treatment.

In other cases occurring in the United States of America, mottle-leaf has been successfully corrected with heavy dressings of iron sulphate. More recently it has been shown that the beneficial results derived from iron sulphate were due to zinc impurity in the iron sulphate employed. At present experiments are being conducted with dressings, injections and sprays of zinc sulphate. The treatments have shown promise, but are only in the experimental stage, and in many instances have resulted in serious tree injury.

Samuel and Piper have found gray-speck disease of oats occurring in South Australia to be a manganese deficiency disease, and have suggested that mottle-leaf may be in a similar category. Confirmation or otherwise of this suggestion rests in an attempt to grow citrus in the complete absence of manganese, and this is being done by Haas, of the California Agricultural Experiment Station.

Despite the proof that mottle-leaf may be caused by toxic proportions of certain minerals, and by deficiencies of others, there have undoubtedly been cases of the disorder in Australia which have been rectified by normally good soil management. In some Victorian citrus districts mottle-leaf is associated with saline soils, high water table, and lack of soil humus. More careful irrigation methods, whereby the accumulation of salt is avoided and the water table kept reasonably low, have often helped to overcome the trouble in such cases.

In this regard it is also worth noting that the regular growth of green crops greatly assists in controlling a water table, and the turning under of such crops enriches the soil in humus, the lack of which may be a contributing cause to the mottle-leaf.

It is readily apparent that the varying conditions which are found to encourage mottle-leaf do so by virtue of their disturbing effect on the feeding process of the tree. Further to this, good cultural practices, adequate—but not excessive—applications of fertilizers, careful irrigation, green cropping, &c., all assist proper tree nutrition. As to the case of mottle-leaf which has inspired this inquiry, a critical examination of the practices on the grove in question may yield a clue to the most promising line of attack on the problem.

AGRICULTURAL INQUIRIES.

[Replies supplied by Mr. W. J. Spafford, Deputy Director of Agriculture.]

Pinnaroo Conference: What variety of oats of earlier maturity than Algerian is recommended for the Parilla Well District?

After some years of experimenting with a large assortment of varieties of oats, there are few, if any, which have proved superior to Algerian for general purposes, but for special conditions there are some kinds which can be recommended. Early-maturing

sorts are valuable for grazing purposes, but rarely give as heavy a hay-cut as later kinds, and they cannot be expected to give such yields of grain as the varieties which take a little longer to mature. Of the early varieties which have been in the State for some time *Early Burt* is the best for grazing purposes, and makes fair hay, which is, however, a little on the light side. *Palestine* makes fair quality clean-strawed hay, and gives fairly good grain yields, but is liable to suffer a lot of damage if rust is about. *Early Kherson* has persisted but is rather too erratic as a yielder.

If it is essential to have an early variety for the district *Early Burt* is probably the best of the type, but it is doubtful if we have a better variety for the conditions than *Algerian* for general purposes.

[Replies to questions at the Murray Lands East Conference.]

Barley in a Crop Rotation.

In a system of crop rotation is Barley objectionable from any other point of view than dirtying the land?

Barley as a rotation crop in a wheat-growing district is not objectionable from any point of view, provided it is grown in the right position in the rotation, and there is not nearly enough of this cereal grown in the lower rainfall districts of South Australia. Barley growing is bad preparation for all other cereals, and as a consequence should always be followed by at least one year of pasture or by bare fallow before another cereal crop is attempted.

For the district a rotation of cropping, consisting of—

(*a*) bare fallow,
(*b*) wheat,
(*c*) barley,
(*d*) pasture,
(*e*) pasture,

should be workable, although in all probability growing the barley on bare fallow in a rotation of—

(*a*) bare fallow,
(*b*) wheat,
(*c*) pasture,
(*d*) bare fallow,
(*e*) barley,
(*f*) pasture,

would be better.

At Veitch Experimental Farm over the 16-year period ending with 1930, all wheat crops averaged 9 bushels 14lbs. per acre, whilst all barley crops, of which most were grown on stubble land, averaged 13 bushels 4lbs. per acre. At the same farm, for 9 consecutive years, wheat on bare fallow averaged 13 bushels 32lbs. per acre, whilst barley on bare fallow with similar cultivation and manurial treatments as given to the wheat crops, averaged 18 bushels 46lbs. per acre.

Early types of 6-rowed barley grown on fallow would give good yields in the district, and now that the State has embarked upon an export trade in pigs, the grain should sell well as pork.

Barley growing does not encourage weeds on the farm, because it is the best weed-smotherer of any crop which can be successfully grown in most of the wheat-growing districts of South Australia, and it does not foul the land with barley on any farm where correct bare-fallowing practices are followed. There are plenty of farms in the State which have continuously grown considerable areas of barley for upwards of 30 years, and in most cases there is less barley to be seen in the wheat and oat crops on such farms than on plenty of farms which have never grown an acre of barley.

If the land is always fallowed after barley before another kind of crop is grown, either immediately after the crop or after a pasture, it is impossible to foul the land with barley as a weed except from the droppings of horses which have eaten whole barley in the hay or as grain, and then only from droppings at seeding time.

Livestock Carrying Capacity of Murray Mallee Farms.

What would be the result in regard to carrying capacity of farms in the Murray Mallee if a total change-over to grazing were instituted? Would the grazing value diminish from year to year as a result of no cultivation, and, if so, would top-dressing help to maintain the grazing capacity?

There are so many variations in natural conditions obtaining in different parts of the Murray Mallee that it is quite impossible to give a detailed answer to the question in a short statement. The average annual rainfall varies from over 17½in. at Coonalpyn to just over 9½in. at Waikerie, and soils comprise all classes between clay loams and white sand, and all these variations affect the position.

Without exception the grazing value would commence to diminish a few years after cultivation was stopped and would continue to get less for a varying length of time, in some cases reaching stability quickly, in others taking a number of years.

In the better parts of the Murray Mallee, the deterioration would be rapid, but not so very great, because plenty of useful grazing plants would persist, and in these localities the regular top-dressing of the land with superphosphate would greatly increase the quantity and quality of the pasture and render the holdings really good grazing country. At present prices, and where the average annual rainfall is 15in. and upwards, the equivalent of 60lbs. to 80lbs. superphosphate per acre per year should prove an economic dressing, but the grazing value of farms would be considerably increased if some of the fields were seeded down to lucerne, and if Wimmera Rye grass and King Island Melilot were scattered over the fields. The top-dressing should be done with a drill, with the hoes scratching the surface of the soil, rather than with a revolving broadcasting machine.

Where the average annual rainfall is about 13in. to 14in., the deterioration of the pastures will be greater than in the higher rainfall parts of the district, and it will be necessary to seed the land to fodder plants as well as top-dress with superphosphate if the grazing returns are to be kept up. For this purpose Wimmera Rye grass and lucerne should be used, the Wimmera Rye grass being spread all over the holdings and lucerne being properly established in some of the fields. In these conditions from 50lbs. to 60lbs. of superphosphate per acre per year should prove a business proposition in existing conditions.

Returns would be increased if portions of the holding were seeded each autumn with cereals, put in with drill or combine at top-dressing time.

The position is much more difficult where the average annual rainfall is about 10in. to 11in., and particularly so on the rubbly-limestone soils, because the deterioration of the pastures is so great on the rubbly-soils, finishing with some spear grass and barley grass, and a lot of the useless squash weed and false samphire, and on the sandy soils consisting almost wholly of barley grass. The top-dressing of such country improves the pastures, but can hardly be made an economic proposition. If cleared land in farm-size areas is to be used wholly for grazing purposes, cereals, and preferably mixtures of two or three kinds, should be drilled in with some superphosphate every autumn on a fairly considerable proportion of the holding. The addition of a little Wimmera Rye grass seed to the drilled area each season would increase the grazing value of the farm, and a few fields seeded to lucerne would be of additional value.

Moisture Holding Ability of Heavy and Stony Land.

Which land retains moisture the longer, heavy land or stony land with sand drifted over it? Is stony land of this description more susceptible to "take-all" and other diseases?

The retention of moisture in soils that are being cropped does not depend so much upon the soil type as it does upon the mechanical condition the soil is in. Any soil with a layer of loose friable soil at the surface will retain moisture longer than one that has been allowed to become set together. If the heavy land, and the stony land covered with sand were both uncultivated, the chances are that the heavy land would lose its moisture first, because of the naturally loose sand acting as a mulch, but there would not be much difference if they were both properly cultivated.

The position is different so far as giving up their moisture to plants is concerned, for on an equal rainfall, the plants will suffer for the want of moisture much sooner on the heavy land than where much sand is present. Plants can continue to collect moisture from coarse, sandy soils without wilting until there is less than 1 per cent. of moisture left in the soil, but heavier-textured soils retain much more moisture, and even in an ordinary clay loam plants will begin to wilt when there is still 14½ per cent. of moisture in the soil, and even sooner than this in a clay soil.

"Take-all" and other foot-rot diseases of wheat are always more likely to occur in soils that do not compact together readily, and as it is extremely difficult to get sand which has drifted over stony land really firm, these diseases will be more prevalent than on any of the heavy land of the district which has been properly cultivated.

Premium for Wheats of High Gluten Content.

In connection with the investigations regarding the gluten content of wheat, recommendations have been made for the discouragement of certain wheats of low gluten content but of high average yield...Has any premium for growing wheats of high gluten content been contemplated?

On several occasions during the past 25 years or so, various local millers have paid a premium for wheats with outstanding bread-making qualities, but so soon as the special circumstances warranting the extra expenditure were removed, they reverted to the practice of purchasing all varieties at f.a.q. By judiciously selecting and blending wheats from certain districts in the State, millers have been able to make flour which suited local requirements admirably, and as Australian wheats, in normal times, have not been sold on the overseas markets in competition with strong-flour wheats, there has been no particular reason why higher prices should have been paid for exceptionally strong-flour wheats. The position is rather different at the present time, for while the farmer could only get f.a.q. prices for whatever quality wheat he produced, he naturally looked for heavy-yielding varieties, with the consequence that quality has been neglected and the standard of the wheats has been lowered. This lowering of the standard of quality has come so gradually that it was almost unnoticed until there was a world's surplus of wheat, with the consequent difficulty of selling anything but the very best at a price comparable with that received by other countries. This change from the old order of selling our wheat readily because of its cleanness, whiteness and brightness of flour and nutty flavour, has led to the awakening of all people interested in the sale of Australian wheat, and there has been a general focussing of attention on the need for improved quality if we are to regain and hold the markets when normal times recur.

Included in this determination to raise quality and because of the difficulty of purchasing sufficient good quality wheat for local requirements, some millers in this State are paying a premium for wheats of good flour strength at the present time, and believe that the practice has come to stay.

Ensilage Versus Hay.

Are any definite figures, or is information available in regard to the relative value of ensilage and oats and/or barley harvested or cut for hay; i.e., *given a crop of either cereal sown for fodder conservation purposes, which system gives the greater feeding value, taking into account the cost of conservation by each system?*

Sufficient work has been done with oats and barley in connection with the harvesting and storing of both crops as hay, silage and matured grain to compare them as *fattening foodstuffs*, but unfortunately there is no known method of calculating a single figure which will adequately express the value of a foodstuff for the production of—

(*a*) milk,

(*b*) eggs,

(*c*) growth in young animals, and

(*d*) fast or heavy work,

and, further, it is quite impossible to put a money value on the succulence retained by silage, and the increased palatability given to foodstuffs when converted into silage.

Assuming that these cereals, oats and barley, are to be conserved in the Caliph district for *fattening or maintenance purposes only*, they can be compared on the number of pounds of starch equivalent per acre still in the fodder stored.

OATS.

1. On the assumption that oats grown on fallow will average 1 ton of hay per acre, as the crop did at Veitch Experimental Farm over a 21-year period, this, with a starch equivalent of 35.2 per cent. equals 788lbs. of starch equivalent per acre.

2. A ton of oaten hay containing 11 per cent of moisture, would weigh 8,668lbs. if cut as green stuff containing 77 per cent. of moisture, as it will when being put into a silo. Allowing 15 per cent. loss in manufacture, 7,368lbs. of silage per acre should be removed from the silo, which, with a starch equivalent of 8.9 per cent. will contain 656lbs. of starch equivalent.

3. Assuming the oat crop to average 15 bushels of grain per acre at Caliph, as it did at Veitch Experimental Farm, the 600lbs. with a starch equivalent of 54.8 per cent. will provide 329lbs. of starch equivalent.

If a 1-ton crop of oaten hay is allowed to mature it will lose weight and when cut will weigh 1,837lbs. If the stock eat two-thirds of the 1,237lbs. of straw left in the field, allowance must be given for 140lbs. of starch equivalent, because the straw contains 17 per cent. of starch equivalent. The grain stored and the straw eaten are worth 469lbs. of starch equivalent.

4. The hay will cost about 16s. 6d. per acre to put into the stack, using Turretfield figures. The silage will cost about 31s. per acre to store in a pit. The grain should cost about 11s. 3d. per acre to bag and put in a shed.

It will be noted that no provision has been made for rendering hay stacks mouse-proof, for overhead charges in connection with pit silo, nor for storing grain in a weevil-proof receptacle, all of which should be considered in connection with conservation of the various forms of fodder.

BARLEY.

Again using yield figures from Veitch Experimental Farm the value of the barley crop stored in different ways is, for *fattening purposes*—

1. 18cwts. of hay per acre with 36 per cent. starch equivalent, contains 726lbs. of starch equivalent.

2. The silage from such a crop, with 9.2 per cent. starch equivalent, contains 610lbs. of starch equivalent.

3. The 17 bushels of grain, with a starch equivalent of 72.7 per cent., carries 620lbs., and two-thirds of the 803lbs. of straw (19 per cent.) contains 102lbs. of starch equivalent, making a total of 722lbs. of starch equivalent in the grain stored and the straw eaten in the field.

4. Costs to store are about 14s. 10d. per acre for hay, about 28s. 2d. per acre for silage and about 12s. 9d. per acre for grain.

Pastures for Hundred of Clinton.

"Clinton" asks: "What would be the most suitable grasses to grow on a mixed farm in the hundred of Clinton?"

Reply—The natural conditions obtaining in the neighbourhood of the township of Price are rather severe for the growing of many kinds of pasture plants, still there are a couple that can be grown fairly well in association with the ordinary cereal-growing practices.

Wimmera Rye Grass.—Unless some fields are to be kept in pasturage, and rested from cropping for several years the best addition you can make to your grazing plants is likely to be Wimmera Rye grass. This grass is a weed that competes well with barley grass, but is much more valuable as a fodder, and once established on a wheat farm persists with the same certainty as most other weeds. It is easily established by drilling about 2lbs. seed per acre in with cereal crops that are to be harvested for grain, and is done by mixing some seed with the superphosphate every time manure is put in the drill.

Lucerne.—If fields are to be rested from cropping for 3 to 5 years Lucerne is the best pasture plant for your conditions. It should be established in a stubble or on fallow, but not with a cereal crop. The seed at the rate of 4lbs. or 5lbs. per acre should be mixed with superphosphate and be drilled in to a shallow depth only. If seeded in a stubble a disc-drill is necessary to do the job but any seed-drill or combine is suitable for seeding on fallowed land. It is essential if portion of a field is seeded that it be fenced off, as no one has succeeded in establishing 20 acres of lucerne in a 200 acre field.

Other than Wimmera Rye grass and Lucerne the only grazing plants worth consideration are likely to be cereals drilled in early, although if the fields which now grow Burr Clover be top dressed, in the autumn of the year when they are to be left out as pasture, the chances are they would grow as much pasturage as if cereals were seeded into the land. Superphosphate at the rate of ½cwt. per acre per year would activate the burr clover very considerably.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

Pinnaroo Line Bureau Conferences: How much sulphur is it advisable to feed to a working horse?

Reply—Horses are unlike other farm stock—cattle, sheep and pigs—in that they are only required for work, and not to produce such products as milk, meat or wool. For this reason, and because they are not quickly maturing animals, their mineral requirements are comparatively low, and are present in an average ration. Horses do not suffer from a deficiency of sulphur in their ration, and it is, therefore, not advisable to feed this mineral to them.

SPLIT IN TRUNK OF NECTARINE TREE.

Asking how to treat a bad split in the main arms of a five-year-old nectarine, the Secretary of the Snowtown Branch of the Agricultural Bureau has been advised by the Deputy Chief Horticultural Instructor (Mr. A. G. Strickland) that putting a bolt through the split portion is the best means of dealing with the trouble. Before drawing the split portion together by means of a bolt, the exposed wood and inner bark should be trimmed to a fresh living surface, so that when the two surfaces are made to meet, there will be an opportunity for them to heal together. After drawing the two portions of the trunk together, anoint the exterior of the treated part with grafting wax or a bituminous compound such as "Colas." If the latter is used, care should be taken to prevent the material running down between the two joined trunk portions, as in such case, the knitting of the two sections may be prevented.

ACTIVITIES AT ROSEWORTHY AGRICULTURAL COLLEGE, 1933-34.

[By A. R. CALLAGHAN, D.Phil., B.Sc. (Oxon.), B.Sc.Agr. (Syd.), Principal.]

PART V.—LIVESTOCK IMPROVEMENT.

During the year some very valuable additions were made to College stud stock, and it is fitting and proper that these additions should be recorded, for it is at least expected that their influence on the future quality of College livestock will be marked by substantial improvement. A genuine effort was made during the year to lay the foundations for future improvement, and the question of purchasing suitable and reliable sires was the first consideration. In this regard, I am pleased to be able to report that satisfactory purchases were made, all of which should lead to a definite advance in quality. The Clydesdale colt "Cyrus" was imported from New Zealand, two young Jersey bulls of known and well reputed blood lines were acquired locally, and a very fine Southdown ram was imported from New Zealand. Other purchases were made, all of which are herein recorded.

THE CLYDESDALE STUD.

Two important acquisitions to the Clydesdale horses at the College were made during the year in the colt "Cyrus" and the mare "Kowai Gyp." The old stallion, Bangaroo Laddie, was sold by auction at the July sales of 1933.

Cyrus (imp. from New Zealand 2455 N.Z.C.S.B.) was born on January 1st, 1931, and was bred by Mr. Alex. Hunter, of the Moore Hunter Estate, Hawera, New Zealand. He was inspected and bought on behalf of the College by Mr. Tom McKay, of Kadina, at the instigation of the Minister of Agriculture, Hon. S. Whitford, M.L.C. Cyrus is by Bonnie Dene out of Frills; his dam was also by Bonnie Dene as shown in his full pedigree cited on next page.

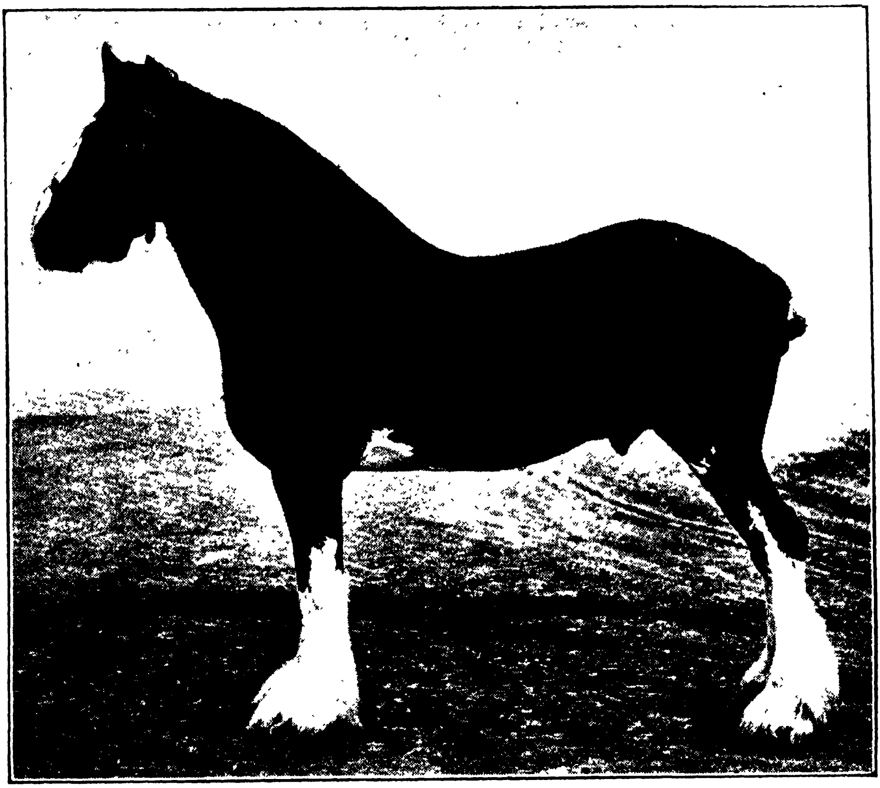
			Bathgate 28223	Baron Ruby 11268
				Jean of Carinstone 16288

From the pedigree it will be observed that Cyrus comes from a line of Clydesdales which is famous in Scotland to-day, for his sire, Bonnie Dene, is by Bonnie Bucklyvie, and his dam, Frills, is also by Bonnie Dene out of a Bucklyvie mare. It is claimed for Bonnie Bucklyvie that the first eight prize-winning sires in England and Scotland at the moment are sons, or out of mares, of which he is the sire.

Since his arrival Cyrus has made wonderful progress, as indicated by the photograph published here, which was taken in August of this year.

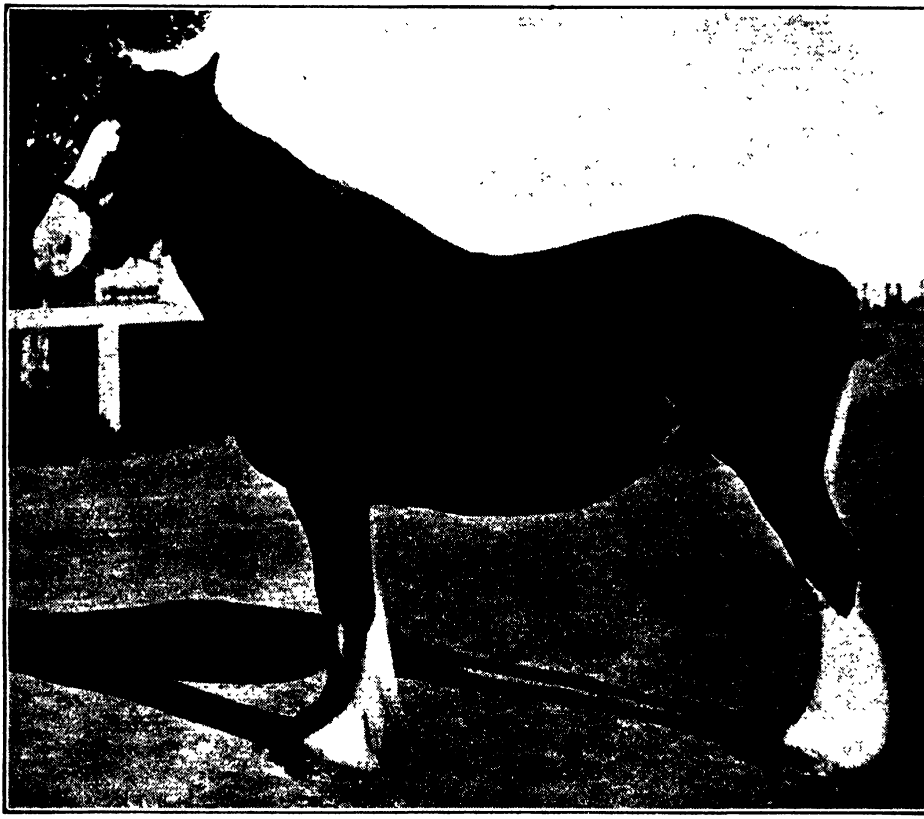


CYRUS (imp.), by Bonnie Dene from Frills. The photograph was taken when he was 3 years and 7 months old.

No attempt to describe the horse will satisfy the multitude of horse judges pervading the country, but an independent opinion which appeared in the *New Zealand Farmer* at the time of his purchase should be of interest to all; for this reason the following extract is given:—"Like the Royal champion colts of both the New Zealand and Sydney Royal Shows of the present season Cyrus is bred on the popular Bonnie Dene-Buchlyvie's Favourite cross, but in addition he is one of the most intensely bred colts of his class yet produced in the Dominion. Cyrus is not only sired by the great breeding horse Bonnie Dene, but he is also out of a daughter of the same sire in the champion mare Frills, winner of the Union Steamship Company's cup. Frills is from another noted prize winning mare in Lingerie by Buchlyvie's Favourite (imp.), while her granddam is that illustrious imported prize-winning mare Hinemoa, which founded one of the most notable lines of Clydesdales of the best type. Cyrus is a rare type of Clydesdale colt, with bone, feet, and ankles of the highest class, a grand outlook, ample weight and substance for his age, and is a close moving, active horse, and has every credential for an outstanding success at the stud. It is seldom that such

intensive breeding is attempted, but in this case Mr. Alex. Hunter has scored an outstanding success."

Another outside opinion was given at the time Cyrus was purchased by a writer in the *Pastoral Review.* Referring to the old-time trade between New Zealand and Australia in Clydesdale horses being renewed, this correspondent states:—"Perhaps the most important sale made recently was that of Cyrus, by that great breeding horse Bonnie Dene (imp.). In addition to being one of the most attractive colts yet bred in the Dominion, Cyrus, who claims all the best merits of the breed, is the result of a unique experiment in the science of breeding, as, in addition to having being sired by Bonnie Dene, his dam, Frills, a noted winner, is also a daughter of that sire. Cyrus is supported also by



KOWAI GYP (imp.), by Ellangowan from Kowai Petal. Rising five year old.

other great strains of blood, as his granddam Lingerie, one of the greatest prize-winning mares in New Zealand, was by Buchlyvie's Favourite (imp.) from the famous old Parorangi foundation mare, Hinemoa (imp.)."

From the College point of view I can say with full confidence that his temperament is unimpeachable, that he is remarkably docile, tractable, and intelligent for his age, yet extremely energetic.

Cyrus is available for service to a limited number of outside mares at a reasonable fee.

Clydesdale Mare, Kowai Gyp (imp.) from New Zealand (5150 N.Z.C.S.B.)—This mare was imported by Mr. Tom McKay, of Kadina, from whom she was acquired by the College. She is a bay mare, was born in November, 1928, and was bred by Mr. James Wyllie, of Sefton, North Canterbury, New Zealand. At present she is in foal to Cyrus.

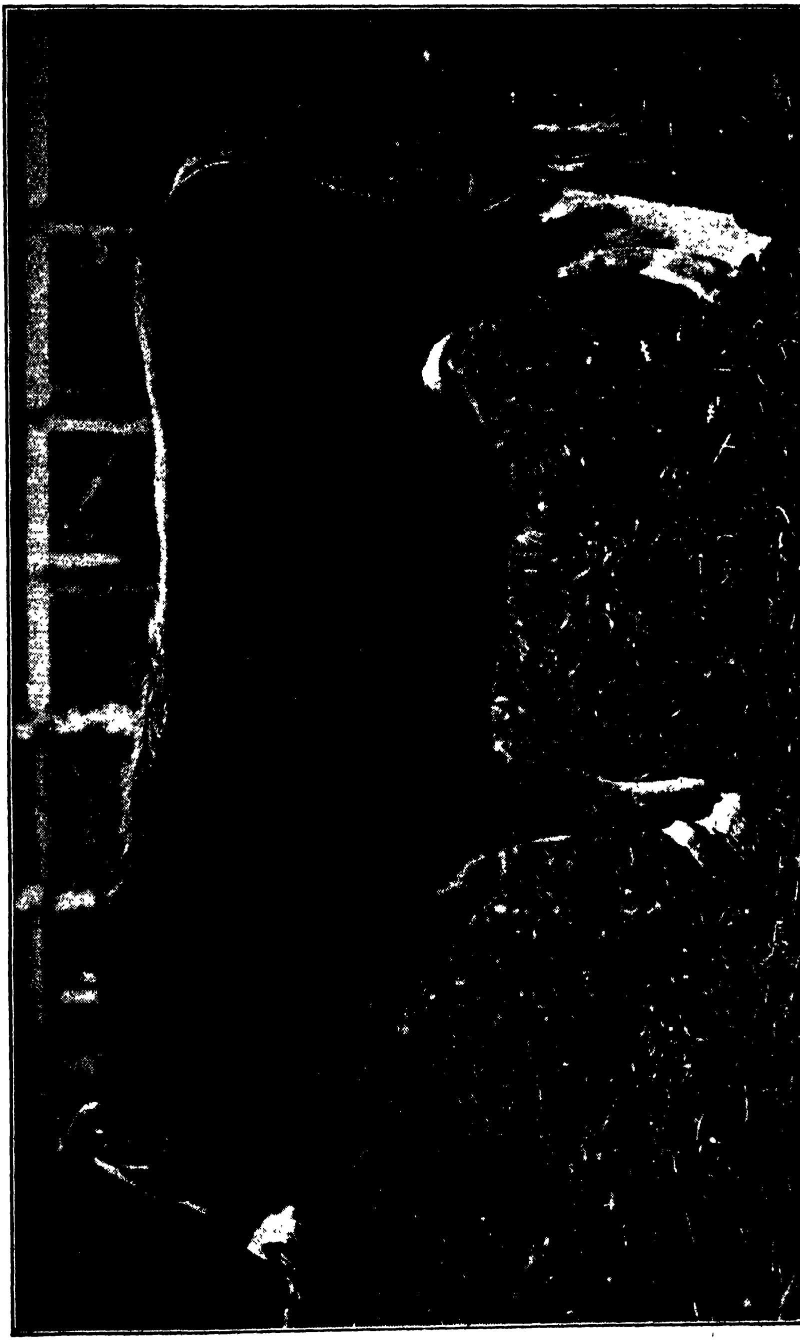
PARA WIRRA PRIDE II., by Para Wirra Collegian from Para Wirra Sweet Iris. The photograph was taken when he was just over 2 years old.



DELMA LILY'S GAMBOGE, by Woodside Agatha's Gamboge from Woodside Lily's Bouquet. Photograph shows the bull at 18 months old.

THE JERSEY STUD.

Through the purchase of the two young Jersey bulls, Delma Lily's Gamboge and Para Wirra Pride II., from Mr. E. W. Pfitzner, Eudunda, and Mr. Howard Dawkins, Gawler River, respectively, valuable additions were made to the College Jersey herd. In addition the cow Hampden Rachel, in calf to Bellefaire Blonde's Aristocrat, was purchased from Mr. J. A. J. Pfitzner, of Eudunda. Through the introduction of this new blood the production of the herd, which is already good, should be improved, but the greatest improvement should be in type, which was a leading consideration when the purchases were being made.

Delma Lily's Gamboge was born on January 17th, 1933, and the photograph reproduced here was taken in August, 1934, when the bull was a little over 18 months old. The bull is of broken colour and of all imported blood, by Woodside Agatha's Gamboge from Woodside Lily's Bouquet (imp. in dam). His dam won the first prize in the three-year-old class at the Adelaide Show, 1933. His sire, Woodside Agatha's Gamboge, was by Old Farm Gamboge (imp.), a first prize winner at the Sydney Show in 1931 and 1933, and a bull that is very well known in Jersey circles throughout New South Wales, while the dam of his sire, Agatha's Sultan Jest (imp.), was a first prize winner at the Sydney Show in 1931.

In the pedigree of the bull, given in full below, appear the names of some of the leading Jerseys which have made the breed famous throughout the world, such as Sybil's Gamboge 9th, Sybil's Successor, Design's Fern Oxford, You'll Do's Volunteer, Blonde's Golden Oxford, Day Dream 10th, and Oxford Sultan of Oaklands twice. It is interesting to note that Oxford Sultan of Oaklands is the grandsire of Brampton Basilua, the cow that last year created the world Jersey record by producing under official test 1,312lbs. of butterfat in 365 days.

Para Wirra Pride II.—This bull is of splendid type with outstandingly good head character. He was bred by Mr. Howard Dawkins, and comes from especially good type stock as well as good producers, and because of his breeding is expected to nick well with the College cows, most of which are descended from a similar blood line to that indicated by the ancestry of Para Wirra Pride II. He was sired by Para Wirra Collegian, and his dam was Para Wirra Sweet Iris. On his sire's side he goes back to the well-known Maglona blood, while the dam of his sire was Cherry of Willow Farm, a cow that was universally admired. The latter tested 485lbs. of butterfat in 273 days. The dam of the bull was by Mercedes Sweet Duke out of Iris of Grantala; this cow, the granddam of the bull acquired, tested 460lbs. and 470lbs. in two consecutive tests over 273 days duration. Acquired from a breeder of such recognised merit as Mr. Howard Dawkins and upon whose opinion as to the suitability of the blood-line was sought, it is felt that this bull will help considerably to obtain refinement of type without in any way prejudicing the good production record of the herd. He was born on July 30th, 1932.

Hampden Rachel.—This cow was born on March 27th, 1929, and was bred by Mr. J. A. J. Pfitzner, of Eudunda, from whom she was acquired. She was sired by Hampden Olives King out of Hampden Rae. One of the conditions of the purchase was that she be in calf to Mr. Pfitzner's well-known bull, Bellefaire Blonde's Aristocrat, which has been breeding particularly well.

THE PIG STUDS.

The outstanding importations to the College pig studs during the year under review were two Canadian Berkshire pigs (a boar and a sow), a Tamworth boar, and two Tamworth sows.

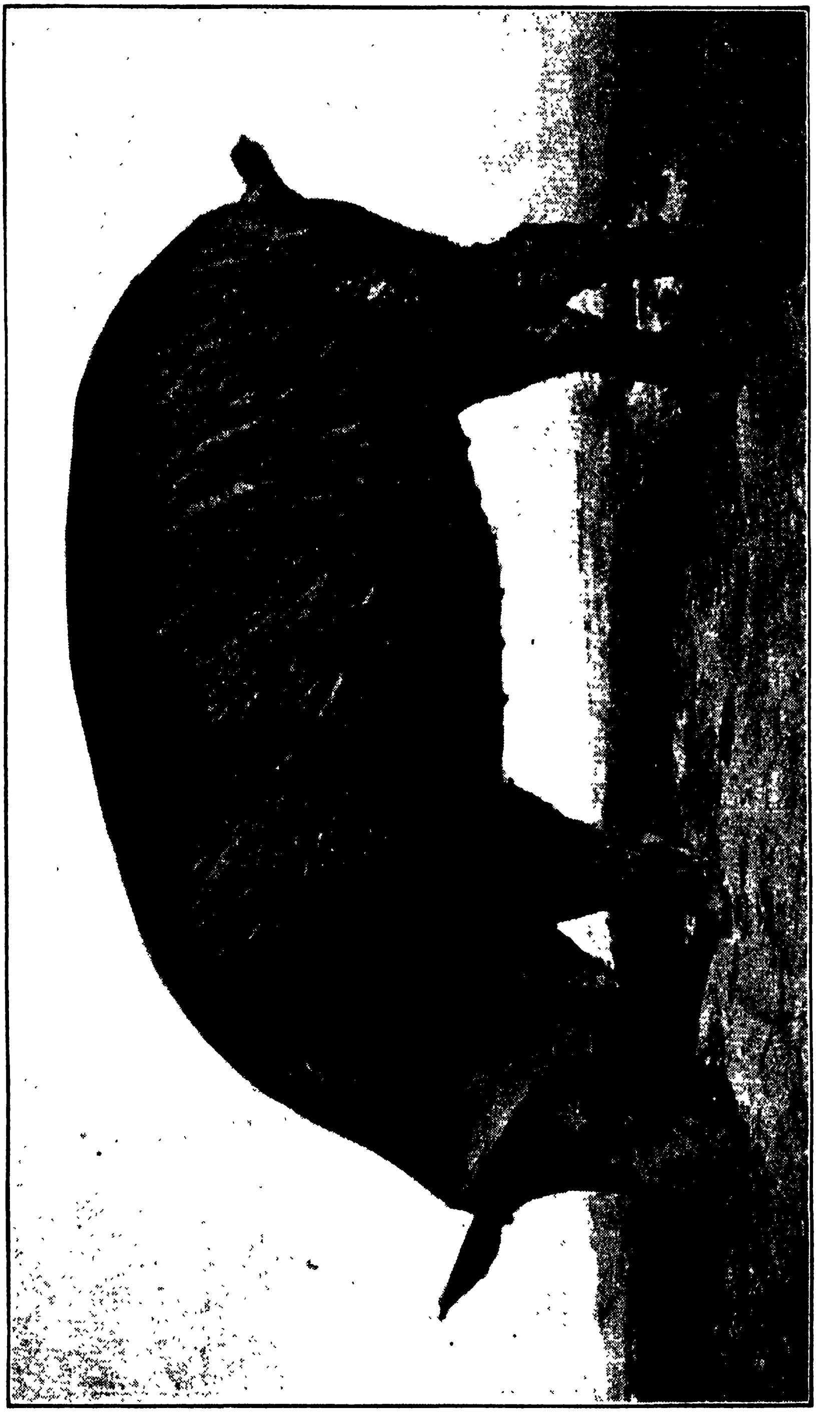
WAITAWA CANADIAN CLARINDER (tmp.) is a pure-blooded Canadian Berkshire Sow.



HAWKESBURY TRIX, one of the young Tamworth Sows purchased during the year.

Owing to the decided change in recent years in the pig market and the general unsuitability of the pure-bred old type Berkshire, it was deemed necessary to discontinue breeding stud pigs of the old strain. Accordingly the Canadian Berkshire boar, Waitawa Canadian Black Prince, and the sow, Waitawa Canadian Clarinder, both bred by Messrs. S. Austin Carr & Co., of Auckland, New Zealand, were imported and arrived in August, 1933. The boar, which was purchased as a weaner, has not grown into a particularly good representative of the breed, and although he is breeding well, especially crossed with our old type sows, he will be replaced by another pure-bred Canadian Berkshire of better type this year. The sow is a splendid type and an excellent mother. Her photograph is reproduced below. Incidentally she farrowed the first litter of pure-bred Canadian Berkshires to be born in Australia in December last.

The Tamworth boar was bred by and acquired from Mr. H. Bartram, of Heidelberg, Victoria, and the two Tamworth sows were bred by the Hawkesbury Agricultural College, New South Wales. The latter two were purchased as weaners and the photograph of one of these sows, Hawkesbury Trix, is reproduced herein.

No fresh blood was introduced into the Large White Stud during the year.

THE SOUTHDOWN STUD.

During the year the Southdown ewes were carefully graded and the numbers reduced by the sale of several. The demand for flock rams from lamb breeders was high, and all available rams were readily sold. Three ewes were purchased from Mr. S. King (F4), of Fernside, Scott's Creek, Victoria, and a first-class stud ram was imported from New Zealand. Mr. King, of Victoria, kindly purchased the ram "Matatua U96" from Mr. J. Knight (F54, N.Z.F.B.), of New Zealand, on behalf of the College. The ram was sired by "Matatua R167" (5776, N.Z.F.B.) out of a "Matatua" ewe, R163. The photograph was taken at the College in August of this year.

EXPORT COMPETITION LAMBS.

In conclusion, I desire to place on record the achievement of the College in winning the Cooper Cup for the best pen of 15 lambs exported from South Australia through the 1933 Export Competitions arranged by the South Australian Branch of the Australian Society of Breeders of British Sheep. Five entries were submitted, and the results are tabulated below:—

College Entries in Lamb Export Competitions, 1933, Conducted by the S.A. Branch of Society of Breeders of British Sheep.

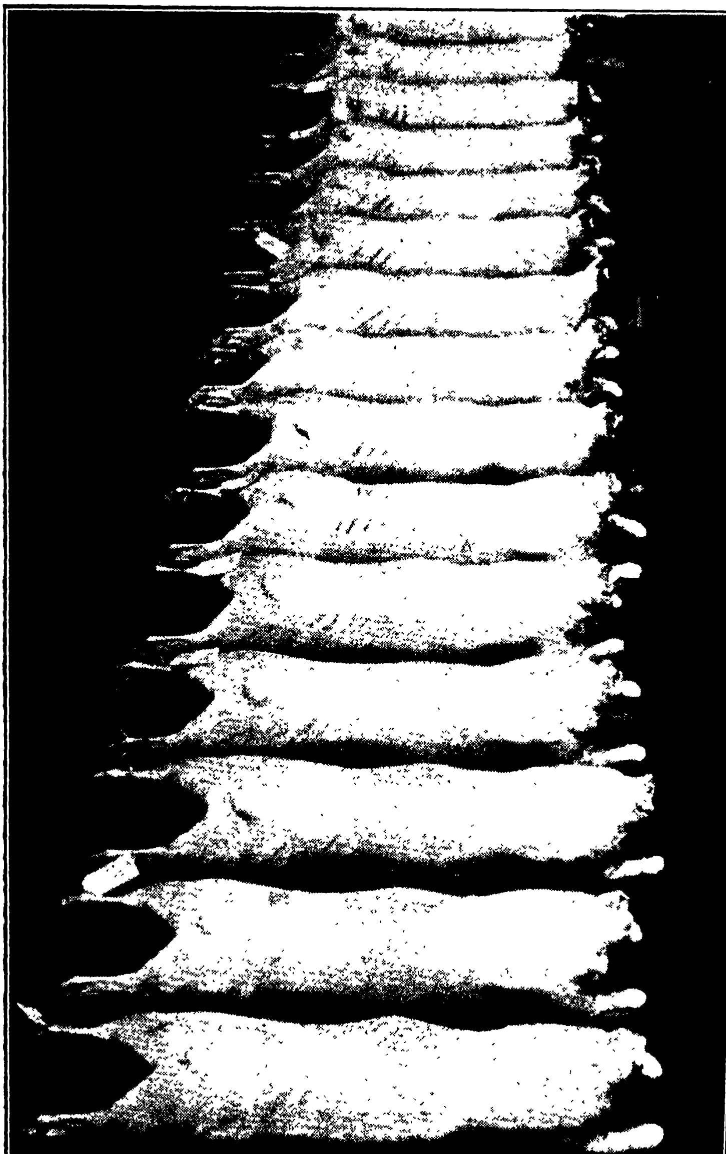
Month	Breed Entered.	No. Exported	Grading.	Points Awarded. Adelaide	Points Awarded. London.	Position.	Total Weight	Net Return Per Head plus 2s. 8d. Skin Value.
								s. d.
July .	Southdown x Dorset Horn Merino	15	All Primo 2	98	99	1st and Cooper Cup	505	19 6
July .	Do.	15	Do.	97	98	3rd ..	519	20 0
Aug.	Do.	15	Do.	93	95	2nd ..	500	19 11
Aug.	Do.	15	Do.	94	94	3rd ..	501	19 11
Sept..	Southdown x Merino	15	Do.	90	96	6th ..	468	17 2

It will be noted that the Dorset-Horn-Merino half-bred ewe figures rather largely in the entries, but last year no other lambs from half-bred ewes were available for the competitions, because the whole of the Border-Leicester-Merino

MATATUA U96 (imp.), the Southdown Stud Ram purchased in New Zealand during the year.

half-bred flock was occupied in experimental work, the lambs from which were shipped independently of the competition. It should not be inferred that the College favours the Dorset-Horn-Merino half-bred in preference to the long wool-Merino half-bred, in point of fact, in most seasons the loss from wool

returns from the Dorset-Horn-Merino half-bred flock in comparison with the Border-Leicester-Merino half-bred is not made up by any extra returns obtained for lambs. It is apparent, however, that the Dorset-Horn-Merino half-bred is a wonderful mother for fat lambs and has the advantage of mating earlier than



Carcasses of the consignment of lambs entered by the College in the 1933 July Export Competition. This entry won the Cooper Cup for the best consignment for the year. The lambs returned 19s. 6d. per head net; this, with the addition of £5 prize money, is brought to a net return of 26s. 2d. per head. Sired by Southdown rams from Dorset Horn-Merino half-bred ewes.

the long-wool half-bred. For this latter reason a producer specialising in fat-lamb production may be able to meet an early market with lambs from a Dorset-Merino half-bred flock and so gain higher prices than if he were solely dependent upon long-wool Merino half-breds.

PARTICULARS OF WINNING GROUP IN EXPORT COMPETITIONS, 1933.

Breeding.—The lambs were by Southdown rams out of half-bred Dorset Horn-Merino ewes.

Age.—They were dropped between March 15th and 25th, 1933, and slaughtered on June 29th. They were thus approximately 14 weeks old.

Two of the Carcasses taken separately of the Cooper Cup lambs. These lamhs were singled out as conforming closely to ideal weight, finish, and conformation.

Weights.—The highest dressed weight was 36lbs. and the lowest 30lbs., and the average for the group 32.93lbs.

Points in Judging.—They were awarded 98 points in Adelaide and 99 in London, making a total of 197 points out of a possible of 200.

PROGRESS OF THE CALF CLUB MOVEMENT IN THE SOUTH-EAST.

[By W. H. Downes, District Dairy Instructor.]

Sutton Town.

Now that a period of more than two years has elapsed since the first Calf Club was formed in the South-East, it is fitting to make some comment on the progress made and the good work accomplished by the operation of this and various other clubs which were brought into being later on in the district.

With the object of forming a club, the first meeting was convened in the Sutton Town School by Messrs. A. C. Bigham, C. Rogers (Head Teacher), and W. H. Downes on March 21st, 1932. At this meeting the history, operation, and objects of the Calf Club movement were fully explained to a representative gathering of parents and pupils. In order to give the matter full consideration, the meeting was finally adjourned until May 17th in the same year, and on this occasion it was unanimously decided to proceed with the formation of a club.

The first consignment of calves for the Sutton Town Calf Club.

Although a nucleus for the club had been formed several years previously by the generous gift of a pure bred Friesian heifer calf from Mrs. H. Walsgott to James Bigham for proficiency in Home Project Work at the Sutton Town School, it was unanimously decided to adopt the breed of Australian Illawarra Shorthorns as a foundation for the club. By means of donations, public subscriptions, and social functions, together with a handsome donation of £10 specially allocated from the School Funds, sufficient money was raised for the purchase of several pure bred calves.

On June 1st, Mr. A. C. Bigham (President) purchased three heifer calves from Messrs. E. and A. Nicholls, the names of the heifers being "Kiama" Beauty, Pansy, and Daphne, at a cost of 15 guineas each. These were dispatched from Adelaide on July 19th, 1932, but, in addition to the original three, the truck contained five other pure breds. One of these was a bull generously donated to the club by Mr. A. Howard, of Mount Barker, and the remaining four, three bulls and a heifer, were purchased outside the confines of the club. This feature proves of special interest, for it showed that the club's activities had directly influenced others in a desire for well bred stock. The first ballot and distribution of calves took place on July 23rd, when out of five applicants, Masters Aubrey

Wilson, Stuart Bigham, and Ervin Bruhn were successful. Mr. C. R. Wilson, father of the first-named boy, in addition to paying the full purchase price for his son's calf, kindly offered to return a calf to the club. The calves, which were all successfully reared, were inspected from time to time by members of the committee. Two further heifers, "Belalie Gypsy" and "Belalie Fussey's Beauty," were secured from Mr. J. McLean for 11 and 9 guineas respectively, and finally allotted to Masters James Bigham and Jock Creek on February 4th, 1933.

The next allotment took place on April 23rd, 1934, when the heifer progeny of "Kiama Pansy," one of the foundation animals, was returned to the club and received by Master Ron Bruhn. Of the other two original heifers, "Kiama Beauty," returned a bull calf, approved by the committee, to the club, while "Kiama Daphne" produced a heifer, and the latter was successfully ballotted for by Master Ross Bigham on June 18th. A further purchase of two heifers was made from Mr. A. Snell, and Miss Betty Bruhn secured "Illawarra Handsome 13th" and Master Zane Wilson obtained "Illawarra Lady May 4th." In order to supply the demands of all members, the purchase of another heifer from Mr.

Mr. James Bigham presented the cow "Fernleigh Pansy" and her two female progeny to the Sutton Town Club.

Snell is in view, and, in addition, a bull calf will probably be selected for the general use of the club. Altogether this club is now in a very strong position, and, besides having most of its members provided for, has at least £40 in hand and is rapidly becoming more or less self-supporting.

Compton Downs.

News of Sutton Town's progress rapidly spread throughout the district, and the next club was formed on May 3rd, 1932, at a meeting convened by members of the Compton Downs School Committee. The writer again had the pleasure of addressing an enthusiastic audience, and it was decided to promote the Compton Downs Dairy Calf Club. For the efficient working of the club, the rules of the Lower Murray Club were adopted with slight alterations. The committee decided to specialise in Friesians, it being considered that this breed was best suited to local cheesemaking requirements. Mrs. H. Walsgott, the only lady member of the committee, deserves special mention for her offer to present a pure bred Friesian heifer to a selected member of the club. In this, Miss Joyce Pettingill was successful, securing for her special care "Fernleigh Pariora Beauty."

Owing to the efforts of the Secretary, Mr. D. E. Wellington, (Head Teacher, and also Secretary of the Blue Lake Home Project Association at that time), ably assisted by a live committee, the club funds benefited to the extent of £70 by a "Back to Compton" function on December 3rd, 1932. Additional calves for allotment were secured in July the following year, one being "Spring Vale Dulcina Inka" from Mr. A. J. Eldridge, Noorat, Victoria, at a cost of 10 guineas, the other, "Willowvale Collantha Triumph" from Mr. E. W. Patterson, of Long Flat, Murray Bridge, priced at 9 guineas. Mr. Eldridge very kindly redonated 10s. to the club. The two heifers were presented to Masters Alex Dew and Ross Pettingill on July 14th. These three calves have been successfully reared by the members to whom they were allotted, and it is expected that the gift calf will be in milk next November.

The position at this school is that, while ample funds are available for the purchase of more calves, there is a limited number of members of suitable age or with proper facilities to receive a calf and rear it. Possibly, also, the decision of the committee to confine their activities to one breed only has caused a slight limitation of members who would perhaps prefer some other breed. During the

Owners, with their stock, belonging to the Sutton Town Club.

last December staff changes, the Secretary, Mr. D. E. Wellington, was transferred to Moorak School, and the work in connection with this club has been ably conducted by his successor, Mr. R. Mathews.

Moorak.

On May 4th, 1932, a representative gathering of residents and pupils at the Moorak School was addressed by the writer on the advantages and operation of Calf Clubs. The meeting was adjourned until June 7th, when Messrs. A. C. Bigham, C. Rogers, R. Smith, and C. R. Wilson, all of the Sutton Town Club, attended. These gentlemen explained the working of their own club and the success which had attended their efforts to date. The raising of funds, securing suitable stock, and the general operations of a club were discussed fully. A committee was formed, Mr. A. H. Kilsby being elected President and Mr. C. McConnon (Head Teacher), Secretary. Following the drawing up of suitable rules, it was resolved to include good grade, as well as pure bred, calves. With the object of securing calves for the club, several of the leading district breeders and dairymen were approached by various members of the committee, with the result that they received promises of 12 well bred, in some cases pure bred, heifers—a highly satisfactory achievement. Those responsible for sponsoring the movement in this

way were Mrs. H. Wallsgott with a gift of two Friesian heifers; Messrs. R. Smith (Friesian); K. McIntosh (Red Poll); W. Hitchcock (Jersey); A. L. Brown (Shorthorn); A. H. Kilsby (Shorthorn); A. P. Spehr (Jersey); S. Clark (Ayrshire); F. Lock (Jersey); and Messrs. E. W. Tollner and R. S. Taylor each an Ayrshire heifer. The allotment of the 12 animals took place on July 8th, 1933, the following being the recipients:—Ralph Bruhn, Kevin Bruhn, Len Newton, Lindsay Lock, Bernice Friedrichs, Keith Brown, Hartley Kilsby, Ron Hamilton, Bill Clark, Mavis Janeway, Douglas and Alan Ferguson. The rules were finally completed at a committee meeting on July 20th.

On October 7th a Calf Show was held at the school and prizes were given in connection with the rearing and handling of the calves, making due allowance according to the difference in ages. All these calves have now been successfully reared. Moorak is to be congratulated for its enterprise in securing so many calves free of cost, but this was made possible only by the unfailing generosity of the donors.

Three pure-bred Friesian heifers in the Compton Downs Club. The largest heifer was a gift from Mrs. H. Walsgott; the other two were allotted recently.

Glencoe East.

The committee of the Glencoe Home Project Club decided to form a Calf Club on July 19th, but only on condition that calves should be purchased at such time as sufficient funds were available. As a means of raising the necessary funds, a Pet Show and Exhibition of School Work was held at the school on August 24th. The effort realised a net £30 and proved so popular and successful that it was repeated with a similar result one year later. With this amount in hand, an advisory committee was formed to draw up rules and to manage the affairs of the club. Those who were associated in this were:—Messrs. F. Childs, President; R. S. Michelmore (Head Teacher), Hon. Secretary; A. J. Riddle, H. Holloway, W. F. Koop, and W. H. Downes. In October of the same year the committee decided to purchase two pure bred Ayrshire heifer calves from Messrs. W. P. Brisbane and Sons, of Gowrie Park, Weerite, Victoria. The two calves agreed upon were "Gowrie Park Sparkle" and "Gowrie Park Lavinia," both from tested cows which had produced well. They were allotted to Masters Ross Holloway and Harold Cram. The Glencoe Club adopted the policy that, instead of confining their activities to one breed only, the individual breed requirements of each member would be studied and the required breed supplied after a ballot had been

taken. The next purchase was a Friesian (pure bred) from Mr. C. J. Morris, of Monteith, South Australia. This heifer, "Murray Glen Griselda 2nd," was allotted to Ronald Childs on April 2nd, 1933. Had it been anything but a Calf Club purchase, it is very doubtful whether the owner would have been disposed to sell this promising youngster, seeing that the dam produced no less than 621lbs. of butterfat as a senior two year old. The young recipient therfore is an extremely lucky boy. Ever since the boys took possession of their calves, they have fed, cared for, and trained them under the guidance of members of the advisory committee. "Gowrie Park Sparkle" has now calved, and it should not be very long before her mate comes into action.

YAHL.

The inaugural meeting of the Yahl Young Farmers' Club was held on July 19th, 1933. Mr. A. C. Bigham, President of the Sutton Town Club, in company with the writer, attended by invitation. After eulogising the value of club work, a unanimous vote was taken in favour of commencing a club. A committee comprising Messrs. A. W. Kilsby, President, R. C. Rowley, Treasurer, A. Prater

The final presentation of the Glencoe Club's first two Ayrshire calves purchased from W. P. Brisbane & Sons, of Gowrie Park, Weerite, Victoria.

(Head Teacher), Secretary, and Messrs. A. A. Hill, F. W. Button, A. Wicks, S. and F. Norman was elected the same evening. The School Committee donated 7 guineas, while a further gift of 5 guineas was received from the Yahl Co-operative Cheese, Butter, and Bacon Company. The committee decided to specialise in Friesians and the first two heifers were eventually purchased from the Spring Vale Stud, owned by Mr. A. J. Eldridge, of Noorat, Victoria, and included "Lassie Patch," priced at 10 guineas, and "Mona Inka," 15 guineas. Mr. Eldridge very kindly redonated 25s. of the purchase price to the club. The calves arrived on October 2nd, 1933, and were balloted to Miss Joyce Lehman and Miss Betty Hill.

The next calf to be purchased was "Cliffside Double Echo" from Mr. H. F. Kleeman, of Mypolonga, for 7 guineas. A special ballot was held, when Master Errol Button drew first right of refusal. The fourth calf was bought from Mr.

T. H. J. Dodd for 5 guineas. "Glen Murray Crusader's Pride" was allotted to Jack Kilsby. The committee usually arranges for calves to be trucked when but a few weeks old, thus giving the successful members an opportunity of rearing the animals themselves on the best lines under the direction of the club. Lectures are held every quarter on some subject relative to the club's activities, and this, apart from its instructive nature, has become quite a social feature. The policy will be for the club to provide as many calves as possible for the applicants, and it is expected that before very long all members' requirements will be supplied. It is significant that prior to the formation of the Yahl Young Farmers' Club very few Friesians were to be seen amongst the herds of that district; now there seems to be a more general trend in favour of this breed.

MILLICENT.

The youngest district club is of quite recent origin, and was formed in connection with the Millicent School. A decision to form a club was reached on June 21st, 1934, and a week later rules and conditions for governing the club

Committee and successful applicants of the Yahl Young Farmers' Club. In the second row are Ivor Dowdell, Max Crouch, and Tom Hall. In the front row are Cliff Lehmann (with "Lassie Patch") and Betty Hill (with "Mona Luka").

were carefully discussed. At this meeting many kind offers of donations were received. The first calf, a pure bred Illawarra Shorthorn heifer calf, was the generous gift of Mr. A. N. McArthur, of Millicent, and this has since been allotted to Ross Kent. Mr. W. S. McAuliffe, of Eudunda, has also kindly promised a gift to the club of a pure bred Jersey bull calf, about three months old, sired by "Eudunda Merry Mike." In addition, Elder Smith & Co. have graciously offered two 100lb. bags of Meggitt's linseed meal for the feeding of the calves. Donations now totalling 11½ guineas are in hand and the purchase of another pure bred calf is contemplated.

The officers constituting this club are:—President, Mr. G. Major; Vice-Presidents, Messrs. R. DeGaris and H. E. Holtzgrefe; Treasurer, Mr. E. J. Mitchell; and Secretary, Mr. G. W. Downes, who is attached to the staff of the

Millicent School. Since its inception the number of people interested in the movement is steadily increasing, and during its brief existence of approximately three months, the club has obtained a very firm footing.

Objects of the Clubs.

In all, there are now six Calf Clubs operating in the district, but it is anticipated that, in view of the excellent work being accomplished, many more clubs will be added to this number in the not far distant future. One of the principal rules applying to Calf Club management makes it practically imperative for the owner members to display their charges at the nearest district show. The work of feeding, training, clipping, cleaning, and the general show preparation of their animals is of the highest educational value to the youngsters, who take a keen and enthusiastic interest in these duties.

Evidence of this has been well demonstrated at the Mount Gambier Annual Show, and the degree of success attending their efforts has not been confined to the Home Project Section alone, but extends to the open classes against all exhibitors. Accommodation on the local grounds last year had to be extended in order to provide sufficient stalls for the 40 or more entries. It is now anticipated that the entries this year will number between 50 and 60 head, so that this surprising increase is likely to more than tax the present arrangements. Clubs endeavour to cater principally for those children whose final intention is to follow a life on the land. Club work gives them an early interest and training in stock questions such as feeding, handling, training, &c., the costs associated with same, and should prove the means of instilling early in life those qualities that make for competent judges of stock. Records appertaining to the work are regularly and faithfully kept by members; the reading of these accounts becomes a regular feature of club meetings and assists in keeping the interest alive. Local clubs have been extremely fortunate in their selection of club leaders, who, without exception, have generously devoted considerable time and energy in furthering the objects of this worthy cause. The assistance rendered by the Education Department has also proved very valuable, particularly as the duties of Secretary are almost invariably undertaken by the Head Teacher in charge. Mr. A. G. Edquist, Inspector of Rural Education, spends much time on this branch of the work and was responsible for much of the ground work in connection with the preparation of suitable rules for governing club work.

The decision of the various Pure Bred Herd Societies to admit Calf Clubs in an honorary capacity has proved extremely helpful to the clubs concerned. Much valuable advice on breeding has been freely given from time to time by many of the stud breeders; for this gracious act the clubs extend their thanks and their gratitude for the interest displayed by these men. The Department of Agriculture also recognises the high value of club work and is rendering every possible assistance to the movement in this State.

Were it not for the ardent and enthusiastic support so splendidly given by town and country people alike, and which assistance is readily acknowledged, it is very doubtful whether our district Calf Clubs generally would be in the thriving position in which they find themselves to-day. Many of these people have no doubt come to realise that the main objectives of the movement are sound in every respect, that the advantages are many, and the results very far-reaching. That the results will prove of ultimate advantage to the prosperity and advancement of the district seems highly creditable, and this should surely prove a means for considerably improving the general standard of our dairy stock. The attainment of this worthy objective seems not only possible, but capable of early achievement largely through the medium of our district Calf Clubs.

ANALYSES OF ARSENATES OF LEAD.

In response to a request made by local manufacturers for the results of analyses of several Arsenate of Lead Spray Compounds procured by the Department of Agriculture last November, the report of the Director of Chemistry is now published. It reads as follows :—

" The samples of Arsenate of Lead Spray Compounds (11), received on November 3rd (10), and November 8th, 1933 (1), No. 342, have been analysed with the following results :—

No.	Brand.	Moisture.	Total Lead (PbO)	Total Arsenic (As_2O_5)	Water Soluble Arsenic (As_2O_5)
		%	%	%	%

11	" Elephant " Paste	46·4	34·3	17·7	0·18

Moisture Free Sample.

Number.	Total Lead (PbO)	Total Arsenic (As_2O_5)	Water Soluble Arsenic (As_2O_5)
	%	%	%
1	62·6	30·9	0·18
2	64·1	31·4	0·13
3	64·4	32·6	0·43
4	64·7	30·8	0·51
5	66·3	31·0	0·34
6	63·9	31·9	0·17
7	64·3	32·5	0·60
8	64·3	31·6	0·37
9	63·9	33·2	0·25
10	63·7	33·0	0·20
11	64·0	33·0	0·34

Suspension Tests.

Number.	Five Minutes.	Thirty Minutes.
	%	%
1	75·5	48·0
2	70·0	50·7
3	24·2	14·1
4	66·3	40·5
5	10·4	5·1
6	18·9	8·5
7	96·5	91·3
8	90·9	86·4
9	79·9	63·2
10	79·5	67·5
11	92·5	74·3

The preparations, with one or two exceptions, show an all round improvement in suspensibility in water, a property of the greatest importance for spraying purposes, as the material remaining in suspension is a true indication of the effectiveness of the spray, and the material settling out of suspension may be regarded as valueless.

STATE OF SOUTH AUSTRALIA.

ORCHARD, VINEYARD, AND MISCELLANEOUS CROP STATISTICS, 1933-34.

[Figures in parentheses refer to previous season.]

[A. W. BOWDEN, Acting Government Statist.]

1. ORCHARDS.

1. *Acreage.*—28,899 (29,109) acres, decrease 210 acres; trees of bearing age 25,640 (25,780) acres. Approximately 964 acres grubbed—mostly in counties Adelaide 418 acres, Hamley 216 acres, Stanley 91 acres, Hindmarsh 35 acres, and Frome 30 acres. New planting 754 acres, was an encouraging feature, chiefly in counties Adelaide 510 acres, Hamley 90 acres, Light 56 acres, and Hindmarsh 30 acres.

2. *Production.*—Generally speaking the crops were an improvement on the previous year, the most notable being:—(*a*) *Apples* 1,002,124 (881,139) bush., an increase of 120,985bush. but 350,140bush. below the record yield of 1,352,264bush. in 1927-28. (*b*) *Oranges* (calendar year 1933), 582,602 (575,046) bush., increase 7,556bush., surpassed the record established the previous year. *Lemons,* 49,028 (40,102) bush. *Other Citrus,* 5,275 (4,420) bush. (*c*) *Pears,* 211,458 (219,576) bush., decrease of only 8,118bush. on the record of 1932-33. (*d*) *Apricots,* 396,993 (331,700) bush., increase 65,293bush., created a record, the previous best being 347,080bush. in 1928-29. (*e*) *Other Fruits*—Plums and prunes 150,539 (182,278) bush., peaches 147,175 (129,908) bush. Details for other fruits are shown in accompanying table.

2. VINEYARDS.

1. *Acreage.*—52,880 (52,479) acres, increase 401 acres; vines of bearing age, 51,042 (51,026) acres. About 869 acres grubbed or died out, chiefly in counties Stanley, 293 acres; Light, 224 acres; Adelaide, 197 acres; River Murray districts, 93 acres; but this was more than counterbalanced by new plantings (about 1,273 acres), chiefly in counties Light, 420 acres; Hamley, 358 acres; Adelaide, 279 acres; and Stanley, 166 acres.

The acreage was described as follows:—For winemaking, 32,451 (33,325) acres; drying, 20,065 (18,668) acres; and table, 364 (486) acres.

2. *Total Grape Yield.*—131,123 (142,917) tons, decrease, 11,794 tons; average per acre of bearing age, 2.57 (2.80) tons. For winemaking, 55,099 (71,885) tons; drying, 75,329 (70,075) tons; and table, 695 (957) tons.

3. *Wine made.*—9,200,000 (12,260,971) gallons, decrease, 3,060,971galls.; and 2,858,307galls. below the average of the previous five seasons, 12,058,307galls.

3. DRIED FRUITS.

1. *Currants.*—160,356 (127,796) cwts.; increase, 32,560cwts.

2. *Raisins.*—Sultanas, 195,119 (200,872) cwts.; decrease, 5,753cwts. on the record yield of the previous season. Other raisins, 54,484 (47,805) cwts.; increase, 6,679cwts.; established a record.

3. *Other Dried Fruits.*—Apricots, 20,623 (18,185) cwts.; plums and prunes, 8,286 (11,540) cwts.; peaches, pears, apples, &c., 12,341 (10,268) cwts.

4. MISCELLANEOUS.

Market gardens, 2,105 (1,896) acres; pumpkins and melons, 310 (341) acres, 1,819 (2,031) tons; tomatoes, 485 (496) acres, 170,292 (174,435) bushels; potatoes, 5,824 (6,454) acres, 19,501 (24,814) tons; onions, 417 (429) acres, 3,008 (3,392) tons; other root crops, 584 (565) acres, 3,216 (3,228) tons; nurseries, 168 (158) acres.

5. Overseas Exports.

The value of the total oversea exports of the products of vineyards and orchards for the year 1933-34 was £1,779,624 (£1,448,915), increase £330,709; the principal items being:—Dried fruits, £822,887 (£612,560); wine, £702,324 (£706,327); apples, £183,698 (£94,460). Complete details of interstate exports are not available, but annually about £600,000 of wine and brandy are exported to the other States.

EGGS IN SHELL AND EGG PULP EXPORTS.

[Compiled from Returns Specially Collected from Exporting Merchants.]

The grand total exports for each of the years 1930-31 to 1933-34 were respectively £156,632, £236,095, £342,925, and £358,056. For the last year, 1933-34, exports constituted a record, and showed an increase of £15,131 over the previous year 1932-33, and £201,424 over the year 1930-31.

The grand total exports of eggs in shell and in pulp in terms of eggs in shell is estimated to have been 3,000,000 dozen for 1930-31, 5,200,000 dozen for 1931-32, 7,300,000 dozen for 1932-33, and 7,900,000 dozen for 1933-34.

Compared with the previous year, there was an increased export of 340,000 dozen eggs in shell to oversea countries, and of 240,000 dozen to the other States. A decrease of 900,000lbs. of egg pulp exported to oversea countries was counter-balanced by an increase of 950,000lbs. to the other States.

Practically the whole export of the eggs and pulp to oversea countries is to the United Kingdom, while that of eggs to other States is chiefly to New South Wales, and of pulp to New South Wales and Victoria.

For the first two months of the current year (1934-35) 629,410 dozen eggs have been exported oversea, compared with 451,590 dozen for the same period in 1933-34.

The following are the details for 1933-34 and 1932-33:—

State.	Eggs in Shell.		Egg Pulp.		Total Value.
	Doz.	£	lbs.	£	£
New South Wales (Ex. B. H.)	828,759	32,893	1,441,382	41,526	74,419

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

PINNAROO LINE PRODUCERS' CONFERENCE.

The Annual Conference of Branches of the Agricultural Bureau situated along the Pinnaroo line was held under the auspices of the Parilla Well Branch at Pinnaroo on September 18th.

Mr. C. H. Lloyd presided and the opening address was delivered by Mr. A. J. A. Koch (Member of the Advisory Board of Agriculture). Delegates were present from the Parilla Well, Parilla, Lameroo, Clanfield, and Parrakie Branches.

Messrs. W. J. Spafford (Deputy Director of Agriculture), Dr. A. R. Callaghan (Principal, Roseworthy Agricultural College), H. B. Barlow (Chief Dairy Instructor), C. F. Anderson (Government Poultry Expert), R. L. Griffiths and P. H. Suter (District Instructors), H. C. Pritchard (General Secretary), and F C. Richards (Assistant Secretray, Agricultural Bureau), represented the Department of Agriculture.

The following papers were read and discussed:—"The Application of locally produced Fuel in reducing Tractor Costs," Mr. E. V. Hammatt (Lameroo); "What of the Farmer of To-morrow?" Mr. M. S. Davis (Pinnaroo); "A Few Ailments Common to Sheep in the Mallee," Mr. R. A. Jenkins (Lameroo); "Breeding and Feeding Pigs for Market," Mr E. A. Davis (Pinnaroo); "Facts that have to be faced during the next Year," Mr. W. J. Morcom (Lameroo).

Departmental officers took part in the discussions and replied to questions.

It was decided that the 1935 Conference should be held at Lameroo.

Mr. C. F. Anderson addressed a combined meeting of the Men's and Women's Branches on the subject, "Poultry Keeping in the Mallee Districts." Delegates were entertained at dinner by the Parilla Well Branch.

A particularly interesting exhibit was staged by Mr. D. Wurfel, of the Parilla Well Branch. This consisted of a collection of wheats in the head, and included varieties from India, Canada, Persia, France, United States of America, Japan, and Egypt.

The evening session was occupied by an address, "Crop Rotations and Live Stock on the Farm," by Dr. A. R. Callaghan.

MURRAY LANDS EAST CONFERENCE.

The Murray Lands East Branches of the Agricultural Bureau held their Annual Conference at Caliph on September 20th.

Mr. S. J. Rundle occupied the chair and Mr. A. J. A. Koch delivered the opening address.

Delegates attended from the Alawoona, Pata, and Taplan Branches, and the Department of Agriculture was represented by Mr. W. J. Spafford (Deputy Director of Agriculture), H. B. Barlow (Chief Dairy Instructor), R. L. Griffiths and P. H. Suter (District Instructors), H. C. Pritchard (General Secretary) and F. C. Richards (Assistant Secretary).

Papers were read by Mr. A. J. Pengilly (Alawoona), "Bulk Handling of Wheat"; Mr. T. W. Wilson (Alawoona), "Calf Rearing"; and Mr. M. Shannon (Pata), "Fat Lamb Raising."

Conference carried the following resolutions:—"That the Government be asked to make provision for a sheep and wool expert to be attached to the Department of Agriculture"; "That the 1935 Conference be held at Alawoona"; "That some system of co-ordination be brought into operation between the Department of Agriculture and the Farmers Assistance Board in the control of the farmers who are working under the Board"; "That a veterinary surgeon be attatched to the staff of the Department of Agriculture, whose services shall be available to the Branches of the Agricultural Bureau"; "That the farmers of this district desire the co-operation of the Advisory Board of Agriculture and the Farmers Assistance Board in order to obtain justice and security of tenure."

At the evening session Mr. W. J. Spafford delivered an address "The Future of Farming in the Murray Mallee."

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

RIVER MURRAY PRUNING COMPETITIONS.

LANGDON PARSONS TROPHY.

This trophy presented by Mr. W. Langdon Parsons will be awarded to the competitor in district competitions who scores the highest aggregate points in both Tree and Vine Sections during the years 1933, 1934, and 1935. The following table shows the position of the competitors:—

Name.	Branch.	1933.	1934.	Total.	
E. A. Liddicoat	Moorook	548	531	1,079	Winner, 1933
A. Wedd	Mypolonga	538	537	1,075

THE IMPORTANT PASTURE PLANTS OF SOUTH AUSTRALIA CONSIDERED AS TO THEIR IDENTIFICATION AND CHARACTERISTICS.

[By E. M. HUTTON, B.Ag.Sc., Field Officer.]

(*Continued from page* 189.)

12. DROOPING-FLOWERED CLOVER (*Trifolium cernuum*).

This is a hairless, prostrate, annual clover, with hollow stems, and the three small leaflet stalks are equal in size as in other true Clovers. The stipules are membranous, with purple veins, the stipule points being green and often divided into two portions. The small pink flowers are borne in small loose heads on long slender flower stalks. The clover takes its name from the ultimate reflexed position of the flowers when the seed is being formed. (See Fig. 35.) The small yellow seeds of this clover can easily be confused with those of Clustered Clover (*Trifolium glomeratum*).

T. C. Dunne and C. A. Gardner, writing in the *Western Australian Journal of Agriculture*, March, 1933, described Drooping-flowered Clover as follows:—"It has become one of the most important clovers in the wetter portions of the State. Like Subterranean Clover, it makes a good stand on virgin soil, but it will thrive in situations which are not sufficiently well drained for Subterranean Clover. Under suitable conditions it is at least as prolific as Subterranean Clover, has less coarse stems, and is probably more palatable to stock. Moreover, it shows considerable resistance to the ravages of the Clover Springtail and Red-legged earth mite—two pests which have played such havoc in many established pastures of Subterranean Clover. Chemical analyses show that the clover is highly nutritious and similar to Subterranean Clover in composition."

This clover makes its maximum growth during September and October, and matures in November. It sheds its seed very freely after maturity. The seed is inedible, and a high percentage are "hard seeds," which will not germinate in one season. Drooping-flowered Clover will only thrive in wet situations which retain moisture well into late spring. Like Strawberry Clover, it will withstand periods of inundation. Under ideal conditions a thick mat of clover up to 18in. high could be expected.

In South Australia this clover would do well in wet situations in the Adelaide Hills and the South-East. At present it occurs naturally only in the wetter portions of the South-East. Western Australia supplies most of the seed used in Australia.

II.—THE MEDICS.

As mentioned previously, both the Medics and Melilots have the central leaflet stalk longer than the other two which are equal. (See Fig. 25, August issue.) A Medic can easily be distinguished from a Melilot by crushing between the fingers, when it will be noticed that a Medic is practically odourless, while a Melilot emits a sweetish scent, due to the presence of a large percentage of a substance called cumarin. In the Medics the flowers are usually yellow, and the seed pods are curved or spirally coiled. The stipules are green and leaf-like.

1. LUCERNE (*Medicago sativa*).

This has been fully described in Bulletin 246 by W. J. Spafford, Deputy Director of Agriculture. Lucerne is easily the most valuable and widely cultivated Medic. In South Australia Hunter River Lucerne is the common one used. Such names as Broadleaf Giant Upright Lucerne and others are trade names for Australian Hunter River Lucerne. Genuine seeds of other strains, such as Grimm, Chinese,

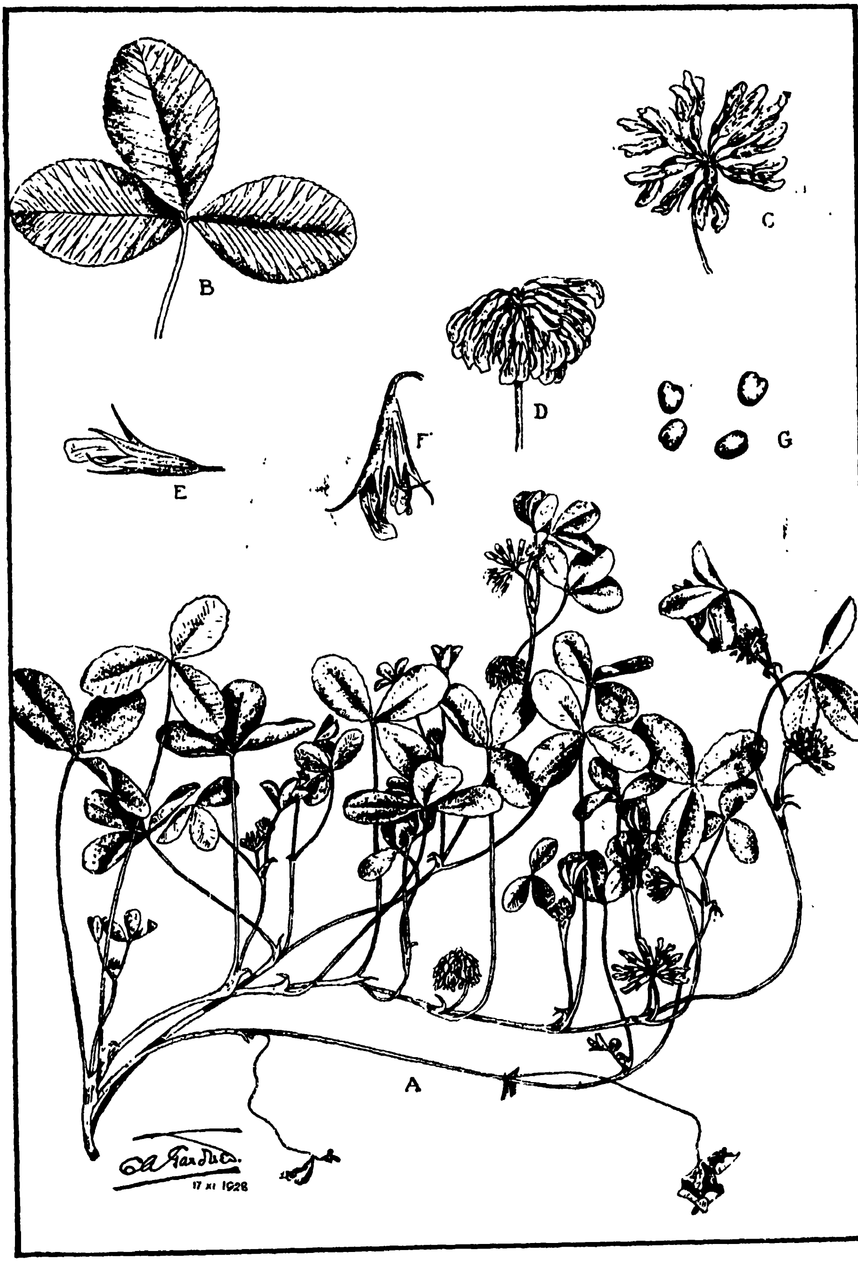

Fig. 35. Drooping-flowered Clover (*Trifolium cernuum*). A. Portion of plant showing ascending habit (½ natural size); B. leaf (natural size); C. flowering head (natural size); D. fruiting head (natural size); E. flower x 4; F. fruiting calyx x 4; G. seeds x 4.

French Provence, and Hairy Peruvian Lucerne are unobtainable in Australia at the present time, "owing to the duty of 9d. per lb. on imported lucerne seed, combined with the primage, sales tax, and the high rates of overseas exchange (25½ per cent.), as well as the fact that all imported lucerne seed has to be stained with rouge before being allowed to enter the Commonwealth" (Brunning's Pasture Book, 1933-34). Mr. Spafford, in his Bulletin, says that "at present it appears that the only type not well-known in the country likely to do as well or better than Hunter River would be Hairy Peruvian."

Lucerne is a sparsely hairy, erect, woody perennial, with the stems arising from the crown, situated at the ground surface. The middle leaflet stalk is longer than the other two equal ones. (See Fig. 36.) The dark-green leaflets, which are toothed at the summit, vary between long narrow and short rounded ones. The stipules are membranous at the base, and possess a green margin and acute green points.

Fig. 36. Australian Lucerne, showing flower-heads opening and in full bloom and seed-heads with some of the seeds just colouring.

[*From "Lucerne Growing in South Australia," by W. J. Spafford.*]

The violet flowers occur in loose clusters. The male (stamens) and female (stigma) parts of the flower lie hidden in the keel, which consists of two petals joined together, and which occupies a position at the centre of the flower. At a certain stage of maturity, or through the agency of bees or other insects, the keel "trips" or breaks open, and the stigma with the attached stamens is shot out. Pollination is then able to occur. It is possible for self-pollination to occur while the stamens and stigma are still enclosed in the keel. Ordinary cross pollination

is much more effective than self-pollination in producing lucerne seed. The seed pods, which contain from two to six kidney-shaped seeds, are twisted spirally into two to four loose coils, open through the centre.

Lucerne is the most drought-resistant legume because of its deep tap-root system, which often penetrates to a depth of 30ft. The main requirements for successful lucerne cultivation are underground water 4ft. to 12ft. from the surface, or an abundance of good irrigation water, good drainage, high average annual temperatures, and sufficient lime and phosphate.

In general, the Adelaide Hills and much of the South-East are unsuitable because of low winter temperatures, the tendency to water-logging in winter, the relatively short growing period, and the abundance of Lucerne Flea. Lucerne roots will not survive below the watertable, because they are not able to respire there. Lucerne thrives in our drier districts, especially where underground water is near the surface, as on the Booborowie flats.

2. BURR MEDIC (*Medicago denticulata*).

Next to Lucerne, this is the most important Medic in South Australia. It is a hairless prostrate annual, with the central leaflet stalk longer than the other two equal ones. A black marking is sometimes present at the base of the leaflets. The

Fig. 37. Burr Medic (*Medicago denticulata*).

[*Leaflet No. 6, N.Z. Dept. Agric.*]

leaflet margins are toothed, and the green stipules are strongly toothed. The loose clusters of two to five small yellow flowers arise in the angle between the leaf and stem. (See Fig. 37.) The seed pods are spirally twisted, the coils being pressed together and provided with hooked spines on the edges, forming the burr which is so troublesome in wool. It owes its wide distribution in the cereal cultivation belt to the nature of its burr, which is easily carried by stock.

It thrives on soils rich in lime, and where the winters are short and mild. It will not grow well where the winters are too long, or where the spring temperatures are too low. It is able to grow in drier situations than other clovers, because

the burrs hold the water a long time once they are saturated, enabling the young seedlings to become established, and because they flower in August and mature early before the hot, dry weather. In a mallee rotation Burr Medic is important in building up the fertility of the soil in the pasture year.

In some years, when climatic conditions are suitable, Burr Medic springs up in great profusion in our Northern districts and Yorke Peninsula. When such a crop is obtained it could be conserved as ensilage. If left, it dies in November and December, and leaves the land strewn with burrs, which provide excellent and often the only sheep feed during the summer months.

3. BARREL MEDIC (*Medicago tribuloides*).

This is a prostrate annual, which may be mistaken for Burr Medic. It differs from Burr Medic in having dark-green, densely hairy leaflets, which are coarsely toothed at the summit. In addition, it has cylindrical burrs, the spines of which are not hooked. It is common in the settled districts, and appears to be becoming as abundant as Burr Medic on the Adelaide Plains.

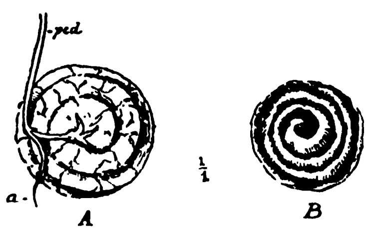

Fig. 38. Showing seed pods of—
A—Button Medic (*Medicago orbicularis*)
B—Snail Medic (*Medicago scutellata*).
[*From Black's "Flora of South Australia."*]

4. SPOTTED MEDIC (*Medicago arabica*).

This is a prostrate, hairless annual, very similar to Burr Medic, except that each of the leaflets are marked with a brown spot in the centre, and the burrs are larger. It is rare near Adelaide, and is commoner in the South-East, being more adapted to temperate conditions.

5. BUTTON MEDIC (*Medicago orbicularis*) and SNAIL MEDIC (*Medicago scutellata*).

The common names of these two Medics are descriptive of the shape of their spineless, straw-coloured seed pods. In Button Medic the pods are flattened and circular, while in Snail Medic the pods are hemispherical, the coils being vertical. (See Fig. 38 A and B.)

They are only found in localised patches in the better districts, because they are less hardy than Burr Medic, and also lack spines, which are the main natural means of spread. Stock tend to eat out these two Medics, because they possess large, very palatable seeds.

Both are prostrate annuals, with entire fleshy stipules. Button Medic is hairless, and possesses smaller leaves than the very hairy Snail Medic.

III.—THE MELILOTS.

They have the central leaflet stalk longer than the other two equal ones, and can be readily distinguished from the Medics by the sweetish scent of cumarin, which they emit when crushed.

Fig. 39. Bokhara Melilot (*Melilotus alba*).

[*From "Grasses and Fodder Plants, N.S.W.," by E. Breakwell.*]

1. KING ISLAND MELILOT, YELLOW MELILOT, HEXHAM SCENT, or CALIFORNIAN LUCERNE (*Melilotus indica*).

This is a hairless, erect annual, and tends to become woody at maturity. The leaflets are toothed near the summit, and the stipules are very small. The small yellow flowers are arranged in long dense clusters. The small pods are one-seeded.

In South Australia it is common on cultivated land and along roadsides. It seems to prefer habitats near the sea, as it is a common weed on the calcareous soils of Yorke Peninsula, and is often found on sandy soil not far from the sea. Also, it had a definite value on King Island, where it converted a barren waste into a fertile and productive piece of country. Stock have to acquire a liking for this relatively unpalatable fodder.

It is an unwelcome impurity in both lucerne hay and wheat because of the odour imparted by the cumarin. W. R. Jewell, in the August *Victorian Journal of Agriculture*, comes to the conclusion that:—

1. Wheat milled with a very small admixture of Melilotus seed produces a tainted flour, the taint persisting in the final loaf.

Fig. 40. Minor Birdsfoot Trefoil (*Lotus corniculatus*). [*After Fream.*]

Fig. 41. Common Vetch (*Vicia sativa*). [*From Black's "Flora of S.A."*]

2. Damp wheat with upwards of 2 per cent. Melilotus, when stored for some time, may yield a tainted flour, even when the Melilotus is separated prior to milling. This does not occur if the wheat is dry.

2. BOKHARA MELILOT or WHITE MELILOT (*Melilotus alba*).

This is an erect, hairless biennial, which becomes decidedly woody. Under favourable conditions it will act as a perennial. It has the usual Melilot characters, and has the white flowers arranged in very long, loose clusters. (See Fig. 39.)

As with King Island Melilot, stock have to acquire a liking for it because of the bitter taste imparted by the cumarin. However, it is much more palatable than King Island Melilot; also, it is a good soil renovator.

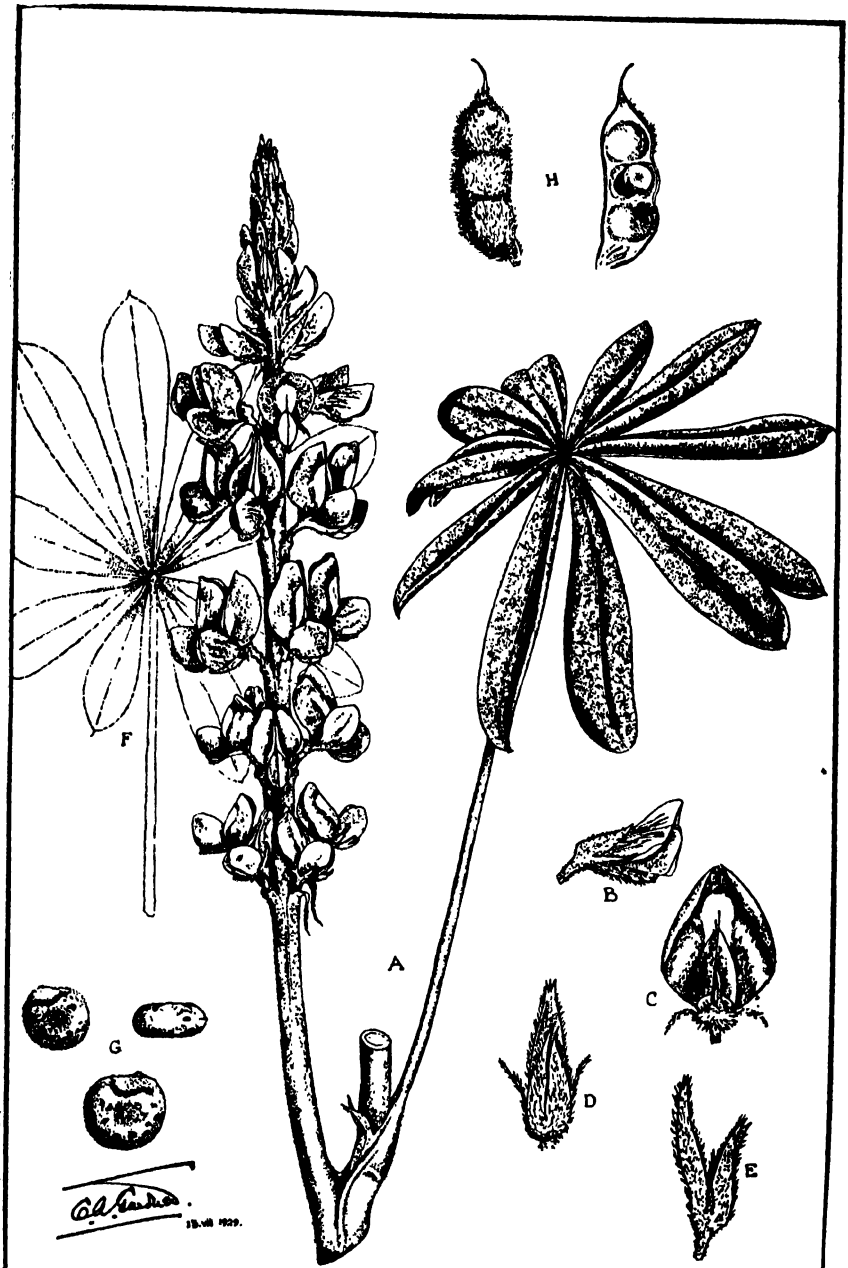

Fig. 42. Western Australian Blue Lupin (*Lupinus pilosus*). A. Flowering raceme and leaf (½ natural size); B. flower (½ natural size); C. flower (¾ natural size); D. and E. calyx—D. from below, E. side view (1½ natural size); F. leaf (½ natural size); G. seeds (natural size); H. seed pod (½ natural size).

[*C. A. Gardner and H. G. Elliott, "W.A. Journ. Agric.," Sept.*, 1929.]

IV.—THE BIRD'S-FOOT TREFOILS.

As mentioned before, these plants possess five leaflets, three of which are close together at the summit of a short leaf-stalk, the other two being at the base and taking the place of the stipules, which are absent. These legumes derive their common name from the fact that the long straight mature pods radiate from the top of a stalk, the arrangement resembling a bird's foot.

The best known Bird's-foot trefoils are Greater Bird's-foot Trefoil (*Lotus major*), Minor Bird's-foot Trefoil (*Lotus corniculatus*), and Boyd's Trefoil (*Lotus angustissimus*). They all make their maximum growth in the summer. The first two are perennials, while the last one is an annual.

Lotus major only thrives under swampy conditions; in fact, it is restricted to soils which retain a considerable amount of moisture close to the surface during the summer months. It is an important swamp species in New Zealand, Victoria and Tasmania, and would thrive in our South-Eastern swampy country.

Lotus corniculatus (see Fig. 40) is much hardier than *Lotus major*, and will produce summer growth under comparatively dry conditions. It occurs naturally in the South-East and Mount Lofty Ranges.

Lotus angustissimus is also a summer grower, and would require summer moisture.

V.—THE VETCHES, OR TARES.

Common Vetch (*Vicia sativa*) is a climbing, hairy annual common on the Adelaide Plains, especially in unstocked natural pastures. It has four to seven pairs of leaflets and branched tendrils. (See Fig. 41.) The flowers are purplish outside and reddish in the centre. The straight pods usually contain eight to ten seeds. Common Vetch soon disappears under grazing, because once the single stem is bitten off at the base the plant dies.

VI.—THE LUPINS.

The Lupins are hairy annuals with at least five folded leaflets radiating from the summit of a single leaf stalk. The common Western Australian Blue Lupin (*Lupinus pilosus*) has nine to eleven leaflets radiating from the summit of each leaf stalk (see Fig. 42); while in another common Blue Lupin (*Lupinus hirsutus*) there are usually five to seven radiating leaflets. The blue flowers are arranged in long clusters.

Lupins grow best on dry sands and light sandy loams. They do not grow well on light calcareous soils. Lupins are exceptionally rich in nitrogenous compounds, and considerably enrich poor sandy soils when ploughed in.

In Europe and America it is not regarded as a fodder plant; in fact, it is described as a poison plant. Stock will not eat the lupin in a green condition if there is an abundance of other green feed, because the plants contain a proportion of a bitter alkaloid, which makes them unpalatable. Under certain conditions of soil, manuring, and storage of green fodder a poisonous substance lupinotoxine is developed, which produces fatal results in stock.

In the summer months the shed lupin seeds are relished by stock, and provide a fattening food. It has been estimated in Western Australia that a lupin paddock will carry and fatten up to four sheep per acre in the summer.

In South Australia very little use is made of lupins. They are found growing in certain sandy localities as along the coast west of Adelaide.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to August 31st, 1934.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to Aug. 30th, 1934.	No. Eggs Laid Month of Sept. 1934.	Total Eggs Laid April 1st, 1933, to Sept. 30th, 1934.
No. 1 test	9,705	850	10,555
No. 2 test	8,914	795	9,709
No. 3 test	8,617	848	9,465
No. 4 test	9,965	788	10,753
No. 5 test	4,801	573	5,374

THE RED-LEGGED EARTH MITE *HALOTYDEUS DESTRUCTOR* (Tucker) IN SOUTH AUSTRALIA: WITH REMARKS UPON *PENTHALEUS MAJOR* (Dugès).

[By D. C. SWAN, B.Sc., Waite Agricultural Research Institute, University of Adelaide.]

A.—HALOTYDEUS DESTRUCTOR.

I.—INTRODUCTION.

Halotydeus destructor has been known as a pest of market crops in South Africa since 1908, and in Western Australia since 1917. During the past few seasons it has reached pest proportions in certain parts of South Australia. Preliminary studies to determine the economic status of the mite in this State were therefore begun at the Waite Institute in the winter of 1933. These were continued during the past (1934) winter, and certain of the observations made are now recorded. The literature contains comparatively little on the biology of the mite, and these inquiries have so far been chiefly directed towards supplementing this side of the problem.

II.—DISTRIBUTION.

The mite was first reported by Jack (1908) in the Cape Province of South Africa; his account was well illustrated, and gave the main features of its biology. It was first investigated in Australia in 1917 (*vide* Newman, 1925, *b*); it was considered by Johnson (1930) to have been introduced into South Western Australia in ship-ballast dumped at Bunbury. A few years later it had spread to most of the south-western part of that State.

A series of reports on the mite by Newman (1920-23 *et seq.*) in Western Australia dealt largely with the economic aspect. Froggatt (1921, p. 34) mentioned that a mite which attacked potatoes, peas, &c., was known in Victoria; it is thus probable that *Halotydeus* was present there then. French (1925) refers to the "pea mite"; doubtless this species is meant. It is not known when the red-legged earth mite first appeared in South Australia; Johnson (1930) was the first to record it, but it is known to have occurred in large numbers at Naracoorte in 1925. It was recorded (Anon., 1930) from Corowa (on the Murray R.) and Henty, in New South Wales. Womersley (1933) recorded it from Victoria, Tasmania, New South Wales, and the Federal Capital Territory. It has thus established itself widely in Australia, though in most places its damage is confined to local areas.

In South Australia it is widely distributed, but is most troublesome on the Adelaide Plains, and in some parts of the South-East. It has been taken at Noarlunga, Lockleys, Gepp's Cross, Mount Barker, Kersbrook, Bordertown, and Naracoorte among other places. Johnson (*loc. cit.*) lists further localities. Generally speaking, it is distributed irregularly through most of the better rainfall areas of the State (*i.e.*, those lying within the 15in. isohyet).

III.—SYSTEMATICS.

The identity of the Red-legged Earth Mite in Australia has been associated with considerable confusion. Jack (1908), in dealing with the mite in the Cape Province of South Africa, did not name the species, but placed it in the family Eupodidae. In 1925, Tucker, also in South Africa, described it as *Penthaleus destructor* n.sp., utilising a manuscript name of Jack's for its specific name. In 1921, however, Froggatt had described a closely similar mite from New South

Wales as *Notophallus bicolor.* The Red-legged Earth Mite of Western Australia was for some years determined as this latter species. Newman (1925, *b*) accepted Tucker's name for the West Australian pest, and distinguished it from Froggatt's eastern Australian species. In 1929 a note in the Journal Commonwealth C.S.I.R. (Anon., 1) stated that the correct name of the mite according to Womersley was *Halotydeus destructor* (Tucker)* and that *Notophallus bicolor* belonged in the genus *Penthaleus*, and now became *Penthaleus bicolor* (Froggatt). Re-descriptions and synonymies of these mites were given by Womersley (1933). Further remarks on the nomenclature of *P. bicolor* will be made in a later section; it is pointed out that this species should now be known as *P. major* (Dugès). Finally, the genera *Penthaleus* and *Halotydeus* have been separated from the Eupodidae; they were placed by Oudemans in 1931 in a new family Penthaleidae.

The main steps in the synonymy of *H. destructor* may therefore be given as follows:—

Family: PENTHALEIDAE Oudemans 1931.
Genus: HALOTYDEUS Berlese 1903.
Syn. *Penthaleus* Koch 1838 (in part).
Notophallus bicolor Froggatt (of Newman, 1923, 1924).
Penthaleus destructor Tucker 1925.
P. destructor (Jack) (Newman 1925).
P. destructor Jack (Anon., C.S.I.R. Journ. II., 1929).
P. destructor Jack (Johnson 1930).

IV.—LIFE HISTORY.

In general the life history of a mite is as follows: eggs are laid which hatch to give individuals resembling the adult, but which possess only three pairs of legs. This stage is known as a *larva;* after the first moult the mite has four pairs of legs and the facies of the adult, but is sexually undeveloped, and lacks the genital orifice; it is then known as a *nymph.* One or more nymphal stages, each separated by a moult, intervene between larva and adult. Final stage nymphs develop into adult males or females.

In the case of *Halotydeus destructor* this general plan is followed. The egg (Fig. 1, a) is bright yellow or orange in colour. It is covered by a tough though flexible chorion (outer coat) which is lined with a delicate inner membrane. The surface of the egg is smooth and shining when moist, but when dry may have a whitish bloom; this is due to the drying of a secretion (? of the oviducts) which sticks the egg to the surface on which it is laid.

Several methods of handling the eggs were tried. The most useful of these was to place them on a piece of filter paper resting on a layer of damp sand in a petri dish. They were kept at constant temperature in biological incubators of various types. Adequate moisture is essential for hatching. Eggs placed on dry filter paper in a sealed vessel over water (e.g. in a desiccator) show no sign of development even in this practically saturated atmosphere. For development to begin, the material on which the eggs are resting must be wetted.

*Inaccuracies that have crept into the literature in regard to the name of this mite are:—(1) The attributing of the authorship of *H. destructor* to Jack instead of Tucker, and (2) the spelling of *Halotydeus* as "*Halotydaeus.*"

The process of hatching is briefly as follows: Water is first absorbed through the chorion, and the egg swells slightly, much as a germinating seed. A longitudinal split occurs along one side of the chorion, which is at first closed by the tightly stretched inner membrane (Fig. 1, b). The latter is ruptured mainly by internal pressure but it is aided by two prominences of the embryonic cuticle, which function as "egg-bursters." These occur in the cephalothoracic region. The embryo, with the rudiments of the appendages already well developed, then protrudes from the chorion (Fig. 1, c); it gradually assumes a dull reddish to purple tinge, and the appendages segment. Finally the fully developed larva waves its legs hesitatingly for a short period, and then steps out of the chorion and runs actively away, testing the surface of the paper at frequent intervals with its mouth parts. The body is more elongated than in the adult mite, and very distinct segmentation is visible, particularly at the posterior end of the abdomen (Fig. 1, e).

A point to be stressed in connection with the development of the egg is its intimate relation with the water supply. Unless the egg remains throughout its incubation in contact with adequate moisture, hatching does not occur. Conversely, excessive wetness under certain circumstances may be unfavourable

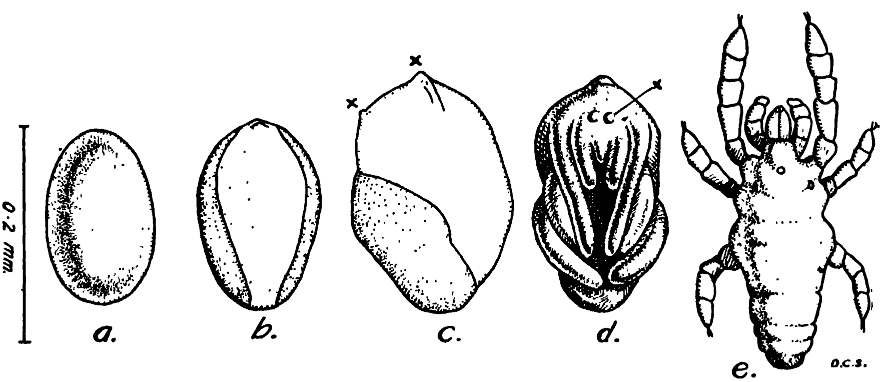

Fig. 1. *H. destructor.* **Development of the egg. (*a*) Egg as laid. (*b*) Chorion split; inner membrane still intact. (*c*) Embryo freed from membranes; egg bursters at X. (*d*) Later stage showing appendages: rudiments of chelicerae (between palps), palps, and three pairs of legs are visible. Egg burster at X. (*e*) Newly emerged larva.**

for development. This appears to be most important where the eggs are exposed to fluctuating temperatures (as in nature). Eggs so affected often swell greatly after the chorion splits; they become globular, due to distention of the inner membrane, and then burst. Many hatching tests failed from this cause. This susceptibility to excess moisture may account for the virtual restriction of the mite in nature to light (sandy or loamy) soils. On heavy soils (e.g. clays) it does not thrive, though it may be present and lay eggs abundantly. Possibly the limiting factor may be the heavy mortality of the eggs resulting from the unsuitable moisture conditions obtaining at the soil surface; these depend upon the physical properties of the soil.

Temperature and Development.—The egg has a short incubation period compared with most insects. The following hatching times were obtained by maintaining eggs at constant temperatures in incubators under moisture conditions kept as favourable as possible. The eggs were laid usually within twelve hours of the start of each test, and many hundreds were used.

Temperature.	Incubation Period. Days.
10° C. (50° F.)	8½
14° C. (57° F.)	6½
17° C. (63° F.)	5
20° C. (68° F.)	4
24° C. (75° F.)	2½

Hatching thus proceeds rapidly at temperatures which greatly slow up the process in *Smynthurus viridis* (the lucerne flea), which is another common pest found with the mite. At 15° C. (59° F.) the eggs of *Smynthurus* take 16 days (*vide* Davidson, 1931). These values indicate that *Halotydeus* thrives at temperatures below the optimum for the lucerne flea. Jack and Tucker (*l.c.*) give the hatching time as 8 days (no temperature specified), but it is probable that retardation occurred, due to inadequate moisture supply to the eggs.

The newly hatched *larva* (Fig. 1, *e*) is 0.25 mm. (1/100th inch) long, and is hardly visible to the unaided eye. It does not assume the black body colour of the adult for several days. It appears to survive best in damp, but well-ventilated situations. For this reason larvae were difficult to maintain in the laboratory; efforts to rear them to the adult stage have not yet been successful. Information on the number of nymphal stages, and the time taken by an individual to reach maturity, is scanty. Tucker (1925) stated that four or five nymphal stages precede the adult. Jack (1908) found that these occurred at intervals of five days; maturity was reached 24 days after hatching. Tucker found that 20 or more days must elapse after hatching before eggs are laid. These periods take no account of temperature.

THE ADULT.—The adult (Fig. 2) has a velvety black body and red legs. The integument is thrown into very fine wrinkles or striae, of which the distance from ridge to ridge is of the order of 1.2μ (Fig. 3, *f*). A double row of feathered setea runs down the dorsal surface near the mid-line. The ventral surface carries more setae, and the legs are well supplied also; all the setae are plumose. The first pair of legs is the longest; as noted by other authors, they are used as tactile organs, as well as for locomotion. The second pair is the shortest. The legs terminate in paired claws, and a median pad (pulvillus) (Fig. 3, *d*). Two ocelli are present; they are situated on the antero-lateral margins of the body. The anus is terminal; the genital aperture is ventral. The latter is large, and flanked by two suckers and numerous setae on each side; it has been described by Tucker (1925). The mouthparts (Fig. 3, *b*) are placed sub-terminally. Five-jointed palps lie at each side of the piercing structures, which consist of paired mandibles (chelicerae) above, and below, a conical structure, the hypostome. The chelicerae are short and powerful, while the hypostome is also strongly muscular. The latter terminates in a number of chitinous papillae, and is bifurcated at the tip.

OVERSUMMERING.

H. destructor is present in the field from the onset of the regular winter rains until the early summer, when it succumbs to higher temperatures and desiccation. In 1933, by the end of October, it could be found with difficulty, and only in sheltered situations. The summer drought is bridged by the egg, as has been shown by Tucker (*l.c.*). This author also found that the dried bodies of mites contained eggs which hatched in the following winter.

The eggs lose water rapidly when exposed to the air, and become deeply concave along one side. When placed on a wet surface, water is taken up by the egg, and in a few hours it resumes its original shape. The writer has had no success in hatching eggs saved from the preceding season. They were kept dry in petri dishes in the laboratory, for periods from six to twelve months. Such eggs often

became bleached, losing most of their orange colour; they burst readily when wetted. It is evident, however, that certain eggs in sheltered situations in the soil or beneath vegetation remain viable through the summer.

Tucker was able to obtain young mites by moistening soil taken from the field in the summer, from places where the mite had been present. The annual plants upon which the eggs are laid die, like the mite, at the approach of summer. The subsequent disintegration of these plants permits this scattering of the eggs, and many must come to rest in suitably sheltered situations.

V.—HABITS IN THE FIELD.

OVIPOSITION.

The eggs are laid almost entirely on the under sides of the food plant, and mostly where these come in contact with, or are close to, the soil surface. Plants having the rosette habit are therefore favoured. In rare cases, where a plant is growing in the midst of a dense crop, the upper leaves may carry some eggs. This has been seen on the leaves of Cape weed (*Cryptostemma calendulaceum*) growing in a crop of peas.

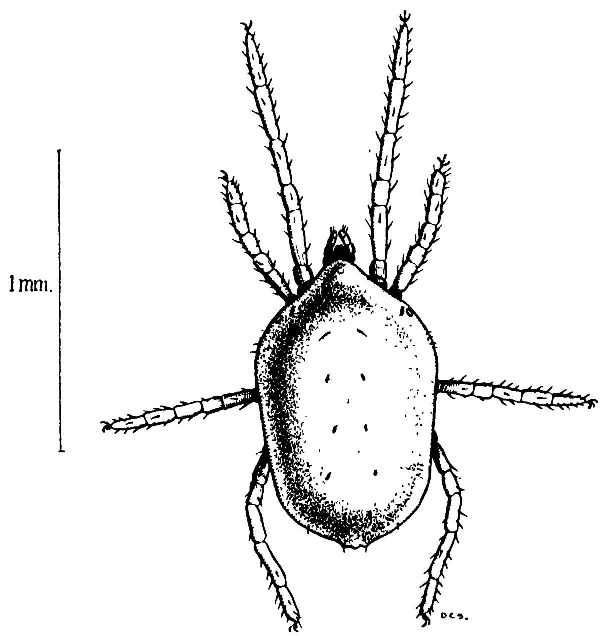

Fig. 2. *Halotydeus destructor.* **Adult female.**

The eggs are laid at random, in a single layer. No webbing is spun over them. They may be so abundant as to cause the under side of a leaf to appear orange in colour. It is not known how many eggs are laid by a single female in her lifetime. The following are counts of the eggs found by dissection in the bodies of a number of mites; 19, 38, 55, 1, 20, 38, 61, 41.

Egg-laying in the field only occurs in suitably damp situations. The process of oviposition has not been observed; the sites chosen preclude this. The mites will not oviposit on a dry surface. Tucker (1925) says that as summer approaches oviposition increases. In the laboratory I have found this to be greatest during the coolest winter months (June-August). As soon as the daily maximum temperature in the laboratory reaches 18°-20° C., egg-laying activity

decreases. Unless the filter paper provided for oviposition was kept moist, no eggs were laid upon it. If the egg-laying surface such as a filter paper or leaf was reversed after oviposition had begun, the mites then laid on the surface newly placed downward. The mites lay both by day and by night, but most eggs are laid in daytime.

In captivity, in uncongenial conditions, the mites may spin fine webbing from point to point over irregularities of the surfaces of their container, and also on the leaves on which they are feeding. In a glass vessel, they often spin patches of smooth white web on its walls, which may in some cases be extended from side to side as loose sheets.

FEEDING HABITS.

When the conditions are suitable, the mites feed at any time, day or night. In bright sunlight they feed on the lower leaves and petioles; in dull light they may ascend to the higher leaves. Their feeding movements are largely determined by the saturation deficit of the atmosphere: the higher this is, the more their range is restricted to sheltered situations. A dense crop of silver beet (*Beta vulgaris* var.) was examined at night. It was heavily infested by *H. destructor,* which was feeding to the tops of the highest leaves, and all parts of the plants were dotted with mites. Under most conditions *H. destructor* is negatively phototropic. This response usually does not deter the mites from feeding in bright light.

The mites are gregarious when feeding—a thick cluster will attack a particular spot on a leaf, gradually enlarging the area of damage, neglecting other parts of the same leaf, or nearby leaves. They prefer broken edges, or injured parts of leaves, to making an entry through intact epidermis.

When undisturbed the mites remain quiescent, feeding in patches on the plant. At the slightest artificial disturbance they move rapidly in all directions, or, more usually, release their hold immediately, and fall to the ground. They are restlessly active when not feeding, and have a characteristic way of running which readily distinguishes them from Tetranychid mites. They congregate on the ground when not feeding, in small hollows on the surface, or beneath leaves resting upon it.

The feeding process is suctorial in nature, but is not comparable with that found in the insect order Hemiptera (bugs, aphides, &c.). When feeding, a mite braces the legs firmly, and applies its mouthparts to the leaf surface. The palps press lightly on the surface, and the hypostomal region is applied firmly. The chelicerae (Fig. 3, *b*) which retain the primitive chelate condition, lie close against the upper surface of the hypostome, and slide alternately back and forth; the sharp and blade-like moveable digit of each pierces the leaf epidermis and reaches the palisade layer. The turgidity of the ruptured cells causes the contents to well out; the tip of the hypostome is applied at this point, and the droplet of plant juices drawn up.

Feeding results in the extraction of the contents of the cells, and marks the leaf in a characteristic fashion. Affected areas of the leaf have a silvery appearance (Fig. 4, *a*) which can be distinguished from the damage produced by the Tetranychid mites, or from that of *Smynthurus viridis,* which is often associated with *Halotydeus.* A leaf damaged by the mite remains opaque when held to the light; the feeding of *Smynthurus* shows as transparent patches. The silvered areas extend as the mites continue feeding; according to the extent to which the contents of the palisade cells have been removed, the leaf assumes a bleached appearance (Fig. 4, *b*). In nature, such leaves rapidly wilt and shrivel, and heavily infested plants may appear as though scorched.

Serial sections of normal and "silvered" leaf tissue of *Sonchus oleraceus* were examined; they showed that the epidermis of the injured leaf was collapsed. The cuticle showed fine breaks at intervals. The cells of the palisade parenchyma layer were largely emptied of their contents, including the chloroplasts. The silvery appearance is due to the replacement by air of the contents of these cells. The epidermis still overlies them closely, and the condition found in the fungus disease "silver-leaf" of plum trees, in which air exists between epidermis and palisade layer, does not obtain (cf. Tetley, 1932).

VI.—ECONOMICS.

H. destructor is chiefly a feeder on annual plants. From observations made in South Australia, it appears to have a strong preference for broad-leaved (Dicotyledonous) plants. Monocotyledons (including grasses) are much less readily attacked.

The food plants may be considered as weeds, pastures, and market crops. Some of the common weeds around Adelaide are preferred food plants. Chief of these is the Cape weed (*Cryptostemma calendulaceum* R. Br.). Others fed on, in order of preference, are:

Sonchus oleraceus L. (Milk-thistle).
Stellaria media L. (Chickweed).
Echium plantagineum L. (Salvation Jane).
Urtica spp. (Nettles).

The following plants appear not to be attacked:

Rumex spp. (Docks).
Emex australis Steinh. (Three-corned Jack).
Malva parviflora L. (Mallow).
Chenopodium spp. (Fat Hen).
Oxalis cernua Thunb. (Soursobs, Sourgrass).

H. destructor has not come under notice in this State as a pest of pastures. In Western Australia it is regarded as being perhaps the chief enemy of the permanent pastures of the South-West of that State (*vide* Section VII.). Permanent pastures in the winter rainfall belt of Australia have been developed by the use of artificial fertilisers; the areas are seeded, chiefly with clovers (e.g. *T. subterraneum*) which are readily attacked by the mite. In an experimental area of permanent pasture at the Waite Institute, consisting chiefly of *Phalaris tuberosa* and *T. subterraneum*, the latter showed during the past spring distinct evidence of injury. The mites feed in clusters on the leaves, which exhibit mottled whitish markings. Experimental injury to *T. subterraneum* is shown in Fig. 5. In this pasture the damage observed in the past two seasons, cannot, except in very local areas, be regarded as serious. It must be pointed out that the soil at the Waite Institute (red brown earth) is heavy compared with much of the podsolised soils of South Western Australia. In the South-East of South Australia, where the mite occurs in market crops, it has not been reported as damaging the extensive areas of clover pastures there; a brief visit to the region in the winter of 1933 did not supply evidence of damage in these pastures.

It has been reported (Anon., 1930) to attack wheat in New South Wales. It has been seen feeding on young wheat at the Waite Institute (October, 1934) but appears to be confined to the edge of the crop adjacent to a headland supporting weeds.

Market crops in South Australia have for the past few years been attacked in certain areas. Tomatoes are grown extensively under glass on the sandy or alluvial soils of the Adelaide Plains. Well established plants are often attacked, but the chief injury is done to seedling transplants. A new transplant takes

several days to establish a root system; mites migrate into the houses from the weeds outside, and during the nights following planting, their numbers may be sufficient completely to wilt the seedlings. A plant reduced to this state rarely recovers. Sometimes all plants in a glasshouse may be destroyed. Other Solanaceae attacked are potato and tobacco. The former has suffered much damage in local areas in the above region, while damage to tobacco is reported in Western Australia (Newman, 1931). Pittman (1930) considers that *H. destructor* may assist to distribute the spores of "downy mildew" of tobacco.

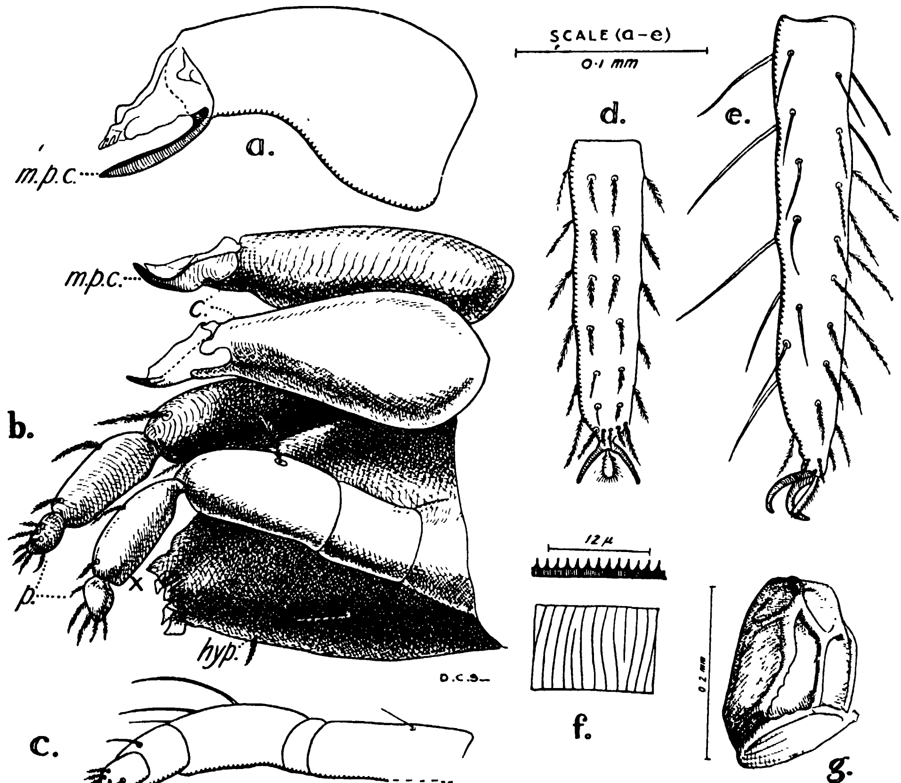

Fig. 3. a. Chelicera of *P. major*. Note bayonet-like moveable process (*m.p.c.*). The fixed process is lightly chitinised. b. Lateral view of the mouthparts of *H. destructor*. The tips of the chelicerae (*C*) normally occupy the position X. The moveable process of the Chelicera (*m.p.c.*) is blade-like; *p*, palps, and *hyp.*, hypostome. c. *P. major*: Palp. from above. d. *H. destructor*. Fore-tarsus. e. *P. major*. Fore-tarsus. f. Cross section and surface view of integument of *H. destructor*. g. Egg of *P. major*. The basal cap is formed from the secretion which holds it to the leaf, and is variable in form.

Legumes (Papilionaceae) include many favoured food plants. Garden and field peas (*Pisum sativum*) and sweat peas (*Lathyrus odoratus*) are specially liable to attack. Mites may do so much damage to the primary shoot of such plants when it shows above ground, that it may not be sufficiently vigorous to grow away. An area of six acres of peas was inspected in August 1933 near Adelaide (Gepp's Cross). It was in the midst of a weedy paddock in which the mite was common. The plants remained short and stunted, about one inch high. A small protected area planted at the same time stood nearly twelve inches high. At Bordertown a crop of 70 acres of field peas was inspected in September 1933. These were fully grown, but the mites were feeding all over the plants

(in dull weather) including the flowers and young pods. The pods failed in many cases to develop, greatly reducing the yield of seed for which the crop was grown. Usually vigorous plants of most species can withstand the mites, and still produce a crop. It is when they are heavily attacked at an early growth stage that the effect is most serious.

Other market crops severely affected are lettuce (*Lactuca sativa* L.), beet (*Beta vulgaris* L.) also its variety, silver beet, and to a lesser extent most other broad-leaved market crops. Silver beet is in the writer's experience probably the most favoured local food plant of the mite. It tends to desert other plants in the vicinity and congregate where this is growing. Silver beet is very little cultivated in South Australia. Ornamental annuals attacked include *Viola* spp., and *Ranunculus*. Many other plants have been listed by Jack, Tucker and Newman.

Thus at present the problem in South Australia appears to be confined largely to market crops and to ornamental plants. The position in regard to pastures as it occurs in Western Australia, appears not to have developed.

VII.—CONTROL.

Given an adequate food supply, the numbers of *H. destructor* respond in the usual fashion, to the influence of weather. In the case of this species temperature is a limiting factor in the spring and summer; in the period of optimum temperatures (late autumn to spring) rainfall may affect the population. Thus during the winter of 1933, the mite was very troublesome on the Adelaide Plains; the rainfall was rather above the average. During the past (1934) winter, mites were little in evidence until the beginning of August, owing to the exceptionally late onset of the winter rains. In 1933, tomatoes in glasshouses in this region were much attacked; in 1934 no damage was done.

No natural enemy of the mite is known; various fellow inhabitants of the soil surface doubtless take some toll, but none appears to be worth mention.

All previous writers have stressed the value of clean cultivation in keeping down the numbers of *H. destructor*. Most of its breeding takes places among weeds; an open-growing market crop provides little shelter for the eggs. The mites move back and forth between weeds and crop. This is specially so with glasshouses, in which breeding conditions are usually unsuitable. Weed-control as far back as possible from cultivated crops is therefore an essential beginning to control of the mite. Weed-killers such as sodium chlorate might be used with advantage in this connection.

Control measures are most practicable in small areas, such as market and home gardens. Probably the most efficient time to spray or dust is about a fortnight after the winter rains have set in; the newly hatched young from the oversummering eggs will be attacked before they reach maturity.

It has been indicated that the mites do most damage to young plants. Where control measures are undertaken these should be directed towards checking the mite at this period, to enable the plants to establish themselves; the latter are then more fitted to withstand later attacks. Successful establishment of young tomato plants in glasshouses in the face of heavy mite attack was obtained by one grower by spraying with nicotine sulphate. The treatment was repeated at intervals of three days.

Tobacco wash was found by Jack (1908) to be a satisfactory spray. Tucker (1925) also found tobacco extract (1 in 80) to be effective. Newman (1923) gives the following formula:—

Tobacco waste	1lb.
Water	2 galls.
Washing soap	¼lb.

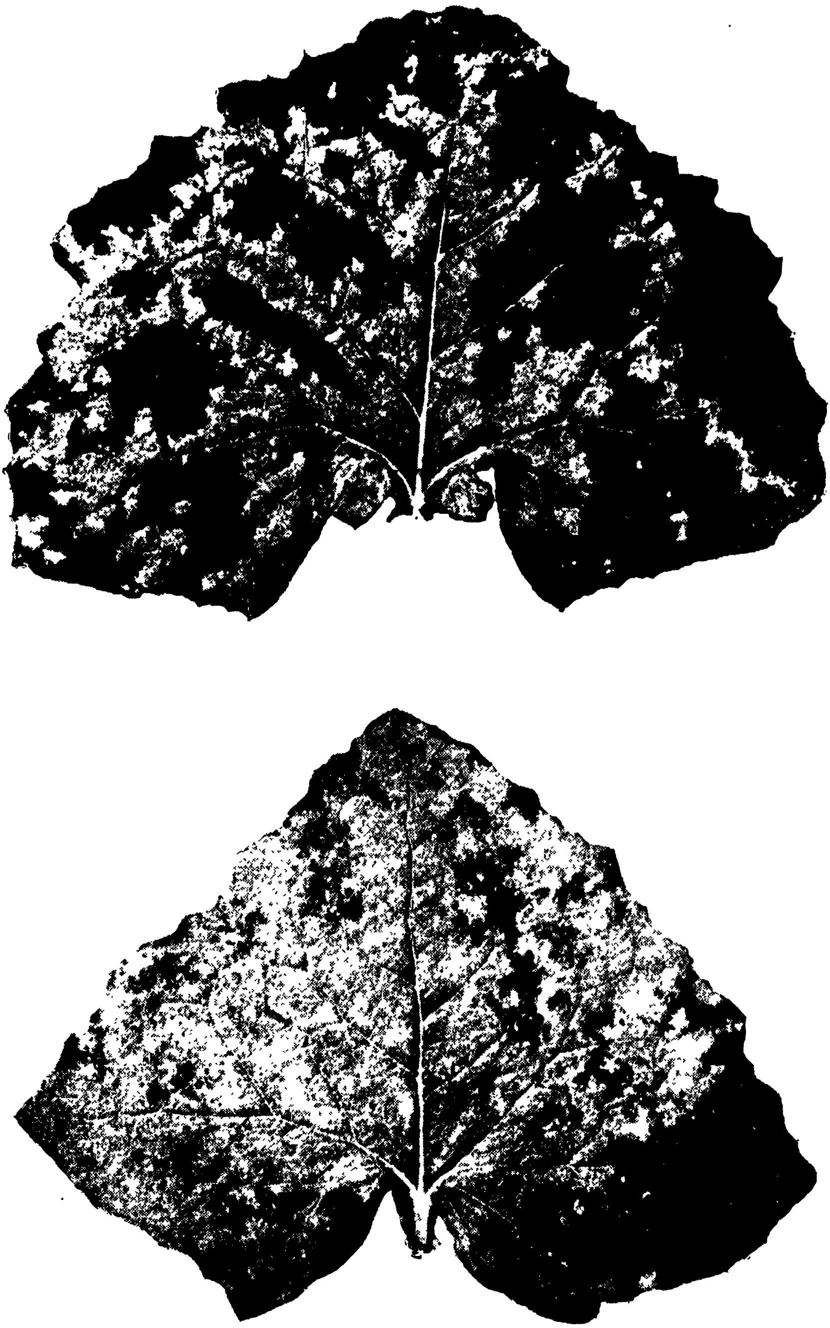

Fig. 4. **Injury to leaves of *Sonchus oleraceus* caused by *H. destructor* (produced by exposing leaf to large numbers of mites in laboratory). *Above*: Early stage. *Below*: After two days' feeding. The epidermis is not visibly broken, and the leaves are still opaque when held to the light.**

The advantage of nicotine and nicotine sulphate sprays is that they do not injure the plant. The killing power of such sprays falls rapidly after application. To obtain full effectiveness, the addition of soap is essential.

Lime-sulphur is well known as an efficient killer of many mites. Ward (1932) stated that control was obtained in Tasmania of *Penthaleus bicolor* (= ? *H. destructor*) when lime-sulphur was used at the strength 1 : 100. We have used lime-sulphur 1:50 in laboratory tests against *H. destructor* and *P. major;* it kills all mites that are wetted, though its action is rather slow. The full efficiency of this spray is not obtained unless a wetting agent is added; *H. destructor* is difficult to wet owing to its fine wrinkled integument (cf. Fig. 3, *f*). Various forms of wetters or spreaders are on the market; soap is not suitable with lime-sulphur.

A pyrethrum extract spray that was tested in the laboratory killed a large proportion of the mites, but appeared to be less effective than lime-sulphur spray, or pyrethrum applied as a dust.

In dense growing crops it is necessary that sprays be carefully directed, in order to reach all parts of the plants. In such cases dusts are often more serviceable; they must be applied when the plants are dry. Nicotine dusts kill mites that are hit, but their action is short, and mites are soon feeding again on the dusted leaves. Pyrethrum dusts have been tested, and kill quickly; the dust used had been diluted 1 : 5 with sulphur. Derris dust also killed well, but did not seem quite so effective as pyrethrum, though its killing power probably lasts longer.

Newman (1925, *b*) recommended a dust made of carbolic powder (4 per cent.) mixed in a carrier such as lime. He also recommended a kerosene emulsion.

Protection of growing plants from infestation by various means has been reported. Tucker employed boards standing on edge and painted with tanglefoot. This kept all mites out, but its lasting quality varies with the degree of exposure, and the amount of dust blown about. Its formula is:—

Resin . . . . 8 parts by weight
Crude castor oil . . . . 5 " " "
A few drops linseed oil (to keep thin).

Warm and stir; do not let boil; apply hot. The residue is re-heated for further applications.

In the case of glasshouses, mites may be kept out by the use of suitable repellents. It is desirable to have a complete wooden border along the base of the walls of the houses. These may be painted with repellent substances (e.g. creosote).

Field tests with any of the foregoing materials have not yet been undertaken in connection with these studies. The preceding survey indicates, however, the methods of treatment that have been recommended. Those that are worthy of further investigation are lime-sulphur sprays and pyrethrum and derris dusts. As the feeding process of *Halotydeus* is suctorial in nature, contact poisons are called for; the possible value of any stomach poison appears not to have been studied.

IN PASTURES.—Newman (1925, *et. seq.*), Gardner and Dunne (1933), and Davies (1933) have indicated the serious nature of the injury done to pasture in Western Australia by *H. destructor*. In pastures control measures present the difficulties found wherever widely distributed pests are concerned.

Newman (1925, *b*) recommends carbolic powder mixed with superphosphate, and applied with a superphosphate spreader. He later (1930, *b*) introduced a spray designed to attack *Smynthurus viridis* (the lucerne flea) and the mite simultaneously. The formula is:—

	Galls.
Lime-sulphur concentrate	5
Proprietary cresol spray	1
Water	250

About 60galls. per acre are used.

Davidson (1933) reported the successful use in South Australia of lime-sulphur (1 : 60, 80galls. per acre) against *Smynthurus viridis*. The crop was grazed or mown short before application, and sprayed after the hatching of the over-summering eggs. Field tests of this method against the Red-legged Earth Mite should be of interest.

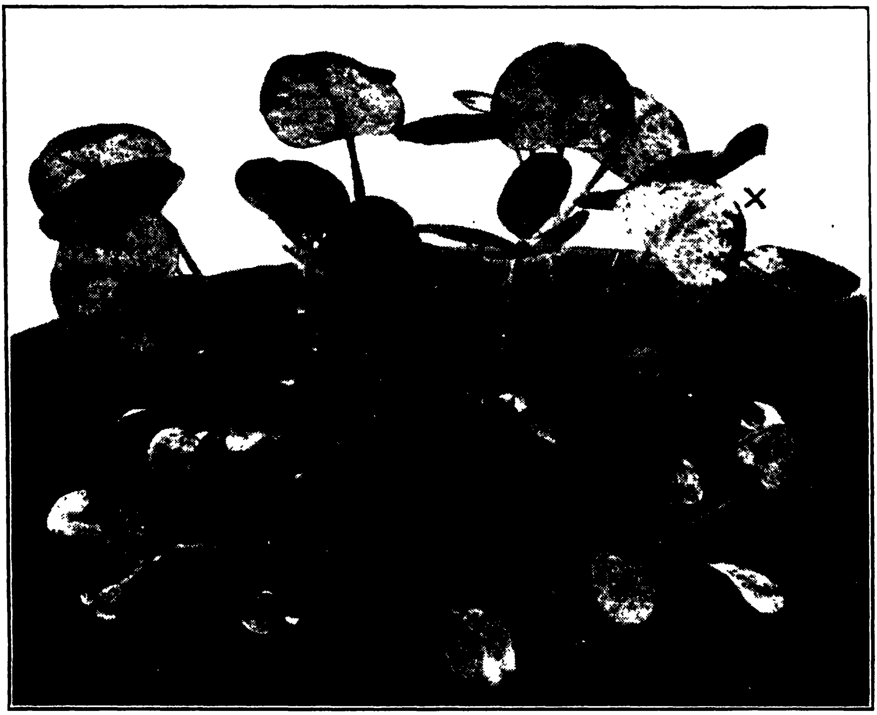

Fig. 5. Injury to Subterranean Clover by *H. destructor*. Note irregularity of damage. A single mite is feeding on leaflet (X).

Gardner and Dunne (1933) recommend burning off an infested pasture in the summer. A creeping fire against the wind is best. This should kill many over-summering eggs, and as the clover burrs are not affected normal germination occurs next autumn. Davies (1933) pointed out that there is evidence in Western Australia indicating that changes in pasture management might be of assistance in reducing damage by the mite. Since perennial grasses suffer much less than clovers, it is desirable to increase the proportion of these in the pasture. The control of Cape Weed in dairy pastures is recommended, as this weed besides favouring the mite, has disadvantages from the pasture and dairy points of view.

A well-kept autumn and early winter fallow should clear an affected area, as in the case of the lucerne flea, since young mites hatching from over-summering eggs are deprived of food.

B.—THE BLUE OAT MITE (PENTHALEUS MAJOR DUGES).

This mite is commonly found in the same situations as *H. destructor*; its habits are very similar, and it is closely related. The following details concerning it are therefore given.

In 1921 Froggatt recorded a mite which was attacking young crops of oats in New South Wales. He described it as a new species, *Notophallus bicolor*, of the family Eupodidae. He did not give details of its biology. The oats were yellowed as a result of its attacks.

Newman originally regarded *H. destructor* in Western Australia as being this species, and reproduced Froggatt's figures in his earliest publication (1923). It was pointed out (Anon., 1930) that *Notophallus bicolor* belongs in the genus *Penthaleus*. Womersley (1933) showed that both *Halotydeus* and *Penthaleus* occur together in Eastern and Western Australia, as well as in South Africa. He also indicated the possibility that *P. bicolor* was synonymous with the European species *P. major* (Dugès). Recently he has been able to confirm this by comparison with specimens of the European form. He has kindly placed this information at my disposal pending its publication elsewhere (Stylops, in press).

The synonymy of *P. major* (modified after Womersley, 1933) may therefore be given as follows:—

Fam.	PENTHALEIDAE Oudemans 1931.
Genus	PENTHALEUS Koch 1838.
Syn.	*Notophallus* Canestrini 1886.
	PENTHALEUS MAJOR (Dugès) 1834.
Syn.	*P. haematopus* (Koch) 1835.
	P. bicolor (Froggatt) 1921.

The characters separating *Penthaleus* from *Halotydeus* were discussed by Womersley (*l.c.*). Briefly they are (1) the anus is dorsal instead of terminal, and (2) the tarsi and terminal segment of the palpi have some plumose setae present; all other setae in *Penthaleus* are simple. In *Halotydeus* all setae are plumose (see Figs. 2, 3, and 6).

The biology of *Penthaleus* has not been studied in detail; it occurs rather sparingly on the Waite Institute estate, and the following observations were made upon it there.

In most situations *Halotydeus* is much the commoner mite; in market crops it may often be obtained exclusively. In cereal crops *Penthaleus* is more commonly met with; the proportions of the two species, if collected, differ according to the nature of the vegetation. The preference of *Halotydeus* for broad-leaved plants has been pointed out; conversely, it would appear that *Penthaleus* favours grasses. Each species will feed on the plants favoured by the other, though much less readily, according to my observations.

The following illustration is taken from a field of mixed *Phalaris tuberosa* and Subterranean Clover at the Waite Institute. The grass grows in dense tufts a foot or more high, and the intervening spaces support the clover. Both mites are present in this pasture. The clover is heavily fed on by *Halotydeus*, while *Penthaleus* is mostly found on the grass, though members of the other species are present in each case. Ten sweeps with a net were made, as far as possible into clover only, and twenty rather larger sweeps into the grass tufts alone. The mites were sorted and counted, as follows:—

	Penthaleus.	*Halotydeus.*
Grass (20 sweeps)	21	21
Clover (10 sweeps)	84	864

Penthaleus major is found in small numbers in dense crops, such as peas, but the writer has not seen damage done to such a crop. Marchal (1908) records it as attacking peas in France, while Malenotti (1925) records it on lettuce in Italy. André (1932), in France, has discussed it in more detail, and has re-figured it.

It was attacking chiefly lettuce. On grasses the mites feed along the leaf blades, favouring the more sheltered leaves in a tussock. They are found singly, the gregarious habit of *Halotydeus* not being manifested. They are less nervous than this species, and do not fall to the ground so readily if disturbed. They move with a more stately measure, lifting the legs high during steps, and do not scurry as does *Halotydeus*. Leaves damaged by their feeding show longitudinal greyish streaks, which turn brown, especially at the tip of the leaf. They do not cause the yellowing characteristic of the feeding of Tetranychid mites; usually in pasture they produce only a slight mottling of the grasses.

Penthaleus major can be distinguished readily from *H. destructor* in the field. The body is purplish-blue, and more rounded than the latter, and has an area of red pigment on the dorsal surface, at the centre of which is the anus. (Fig. 6.) A droplet of clear fluid frequently is found exuding from the anus. The legs are of a deeper red in *Halotydeus*.

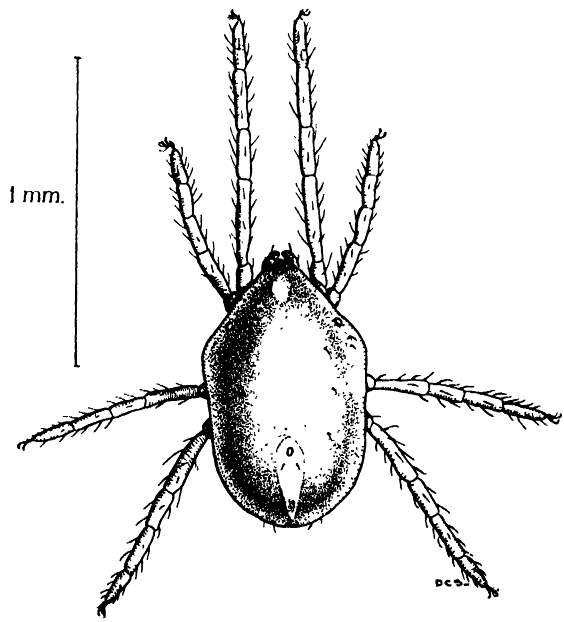

Fig. 6. *Penthaleus major*. **Adult female. Note dorsal anus, in light (red) area at posterior end of body.**

In its biology, so far as it is known, it shows differences from *H. destructor*. The eggs are about half as large again (Fig. 3, *g*), and the outer layer of the chorion is curiously wrinkled. The egg is salmon to whitish-yellow in colour when dry, and deep orange-red when wet. It is laid singly, never in masses, as with *Halotydeus*. *Penthaleus* oviposits mostly under leaves, but it also lays readily on the upper surfaces, and along both sides of upright leaves. It lays few eggs—two to five only were found in the abdomen in microscope preparations. André (1932) gives 3-5 eggs as the number laid. Obviously its power to increase is small compared with *Halotydeus*, assuming the survival rates to be the same.

The hatching of the eggs and life-history generally have not yet been studied. It can be said, however, that as far as it has been observed in South Australia this mite does not appear to be of economic importance. The only exception appears to be its occasional rise to large numbers in young oat crops, as seen in New South Wales. In pastures in the South-East careful searching revealed only isolated individuals.

ACKNOWLEDGMENTS.

The writer is greatly indebted to Dr. J. Davidson for his interest and advice during the course of these inquiries, and to Mr. J. W. Evans, who provided certain of the materials mentioned in Section VIII.

PAPERS READ AT CONFERENCES.

MURRAY LANDS EAST CONFERENCE, KAROONDA, ON July 31st, 1934.

CONCLUSIONS ARRIVED AT FROM 10 YEARS' EXPERIENCE OF MALLEE FARMING.

[By R. Elliot, Kulkawirra.]

While I do not claim to have had as much experience as a wheat grower as some of the other members of this Conference, I have always been observant and during the past 10 years have watched with interest the different phases of crop growth in our district, particularly in relation to wheat growth and disease.

Depth of Ploughing.

The first thing of which I took particular notice was in relation to depth of ploughing. In ploughing a piece of very uneven new land with a 14 disc plough, we found that we were ploughing the banks deeply, and were barely touching the hollows, and when the crop grew, the wheat on the banks was a good crop while in the hollows there was hardly anything, thus pointing to the fact that too shallow ploughing was no good. I have noticed that some of our neighbours who cultivate particularly shallow, seldom have good crops, while those who go in for deeper working usually have much better crops. We have always worked to a fair depth, and have always had fair crops, varying with seasonal conditions.

The first sign of disease which I noticed was in the first wheat crop grown on fallow, and that occurred in small patches in an otherwise healthy crop, which appeared to make very little growth at first, but improved later in the season, and although not so good as the other part of the crop, it ripened rather late, and developed fair grain. These patches appeared at the time to be caused by the surface soil having been blown away in patches. Later in cropping the same paddock, this opinion was confirmed by examining all the weak patches (which were very much larger in the second crop), when the crop was very young, and all these weak patches were on hard ground, from which nearly all the surface soil had blown away. I have noticed the same thing happen in other paddocks, and more particularly in a paddock belonging to a neighbour. This paddock had been well fallowed, worked with a cultivator after a particularly heavy rain during summer, sown in good time, germinated well, and looked well at the start, but soon began to show yellow patches over a large portion of the paddock, particularly on an old track which ran right through the paddock and on which the crop was particularly weak. The state of this crop was brought under the notice of the Department of Agriculture, and two of the officers inspected it. They could find no reason for the trouble except that the soil on these weak patches was rather loose, while on the better portions of the crops, it was much firmer. They attributed the looseness of the soil to deep cultivation, but my opinion is that the real cause was the absence of root growth in those patches owing to the fertile surface of the soil having been blown away. The paddock received the same cultivation all over, yet why the difference in the result? Firming down by ramming with a broad-faced rammer was suggested by one of the officers, and this was tried, but without beneficial result, and the crop finished out very patchy.

Take-all.

Prior to 1932, we had practically no take-all, but in that year we had our first serious experience of it. It started on a wind-blown patch at the end of an old track, and spread over a considerable area of the paddock late in spring. Again in 1933, we had a crop of wheat on well worked fallow. Sown early it germinated well, but soon began to

[*Papers Read at Conferences.*]

show yellow patches. These occurred in all cases on wind-blown patches, and in all cases the plants made poor growth. Later, take-all developed and spread over a large area of the paddock until a crop—which, if it had been normally healthy—would have yielded 10 bags to the acre, finished up by yielding four bags.

We were told when we came here—having had no previous experience of mallee conditions—that we would never be able to grow crops on old waggon tracks, but this was not correct as we had two of them running right through our place. In both cases they have practically disappeared, and have been filled up with drift, showing that crops will grow on land from which the surface soil has been removed if that surface soil be returned or replaced by something of equal value in fertility.

In our light sandy country, we lose more from having the fertile top layer of our soil blown away by the wind than from any other cause, that is in relation to our ability to grow crops, grass, &c. The question is—how to combat the trouble? This can be done to a large extent by correct methods of cultivation, and by using sheep to control weeds. All fallowing should be done as early as possible, not later than the middle of August, subsequent working to follow as soon as possible, and unless the spring is particularly wet and late, all such working finished by the end of September. That ploughing should be of a fair depth—not less than 2½in. in the shallow places, nor more than 4in. at the deepest parts. Very shallow ploughing is a mistake, for during a windy year when only the surface is loosened, practically the whole of the surface blows away, while if ploughed deeper and turned right over, the poorer underlayers are brought to the surface, and it does not matter so much if some of that is blown away.

As economy in production is absolutey necessary, it is essential to confine attention to the acreage which we can work thoroughly at the proper time, and that a thorough working be given directly before seeding.

METHODS OF FALLOWING.

[By G. SUTHERLAND, Copeville.]

There are several reasons for fallowing, chief among them being to clean the ground, aerate the soil, conserve moisture and spread the work more evenly throughout the year.

To grow crops successfully and profitably, it is necessary to have a firm bottom for the seed. The crop on loose patches goes off quickly when there is a burst of severe warm weather. Most of the fallowing in the mallee is done too deeply. If we fallowed to a depth of 1½in. to 2in., we would get better results, for if you rip up this country deeply you cannot get it down firm again unless the season is very wet, and we are not blessed with many of these. Again, the land is so uneven, that each time it is worked, the cultivator always comes on to the high and low places at a different angle, and therefore the deep working continues.

It does not matter what kind of implement is used for the initial working, so long as the work is done before grass and weeds are too big. I do not favour ploughing so that every weed and blade of grass are turned in. In fact, I prefer the other way. I would sooner see the rubbish and some of the grass left in lumps on top, so that an odd bunch of grass &c. will not die; they will help to keep the soil from drifting.

I used to hold the opinion that the more the fallow drifted the better. I have come to believe that if the drift can be stopped the crop will be more even, for if fallow drifts it blows into holes or hard bare patches, and the soil that is blown from these places banks up over the nearest ridge, and before long a soft drift bank forms, on which the crops soon blight off. A crop off the hard, bare places is not so good as from the fallow that has not blown.

For the initial working I do not, and would not use the heavy share plough, only where the ground has become too hard for a lighter and wider implement, or where it is desired to pull out stumps. The chief objection to the heavy plough is that it is

almost impossible to keep it shallow enough on sandy ground. I refer chiefly to the front wheels, the depth adjustment on them being the collar with a set screw on the standard or upright part of the axle. Where the ground varies, and which it does several times in a round on most farms in the mallee, the front wheels must be set to a depth at which they will do a job on the firm ground, then when the plough enters the lighter ground, the wheels sink, the depth is increased, and it cannot be avoided.

Latterly, I have been using a light skim plough or combine for the initial working. The skim plough cuts out the soil in small sods, and does not turn much more than half of it; and then, when the paddock is showing a fair tinge of green on it, it is worked again, chiefly cross-ways, which still leaves the ground soddy or lumpy. After one or two workings like that and warm weather approaching, the grass in the lumps dies, but they still hang together and that helps to hold the drift. After harvest, if a rain falls, run over it very lightly, little more than covering the share, and with another working ten days or a fortnight before sowing, the fallow should be in good condition.

DESTRUCTION OF FOXES.

[By W. R. TRESTRAIL, Coomandook.]

Owners of sheep throughout the Murray Mallee have had a very trying time this year with foxes. Not only have many young lambs been destroyed, but full-grown ewes have been killed and eaten. The problem of the fox is a big one in districts where so much natural scrub is still in existence. It provides ideal hiding places for the fox, and often when hungry, a fox will travel 10 miles in search of food. To combat this pest, stern, strong, united methods must be carried out if the fox is to be destroyed. It is desired to stress the necessity for united action. It is no good an odd farmer poisoning and killing on his own property; all landowners must unite at a given period. The best time to destroy the fox is early in the season, during April and May. After June, the fox becomes too cunning to take baits. The best poison to use is strychnine; as much as will cover a sixpenny piece is the ideal dose for each bait.

The different kinds of bait are legion, and most folk have a kind to suit themselves. Perhaps the best obtainable are small birds, such as starlings and parrots. He has an especial liking for parrots. Shoot the parrots, and when warm, slit open the breast with a knife and insert the strychnine. Hang the bird on a wire fence or a dry bush and scatter a few feathers about to attract the fox's attenion. One point in favour of birds as a bait, is that they are not so readily devoured by dogs, and they will not poison magpies and other birds as will other meat baits. Other good baits are the head and liver of a rabbit, head of a fowl, liver of a sheep cut into 1in. cubes and fried in fat, mice, and small fish such as sardines. Handle the baits as little as possible. I keep an old knife and fork for the purpose. The following is a simple way of preparing baits from a piece of caul fat. The fat is melted down, but before it is quite cold again, it is rolled between butterpats or similar pieces of wood into round balls, about the size of large marbles. When the required number of balls has been made, obtain a skewer with a sharp point, and after heating, make a hole in each ball to the required depth. Immediately, by means of a glass dropper, drop in a little dissolved strychnine. If this is done quickly, the cold strychnine will make a self-sealing cap in the warm tallow. When finished, tip the baits into a can of cold water and leave them there all night.

To set any of the above-mentioned baits (with the exception of the birds) drag a trail in the evening of a couple of half-roasted rabbits or a sheep's paunch a few days old. Either tie it to the axle of a vehicle or pull it along with a piece of rope on horseback. If it is from a vehicle, tie as well, a lump of iron to make a definite mark, in order to follow the trail next day. If possible, set the trail on open country and a fallow paddock. Lay the trail about two miles in length and place the baits about 10 chains apart and mark in some manner the place where the bait is placed.

[*Papers Read at Conferences.*]

Partly bury the bait. If the baits are not taken within a week, they should be gathered and burnt. One of the most important methods, and the most successful, is that every dead lamb that is found should be poisoned, especially if the fox has partly eaten it. Cut open the ribs and place strychnine on the liver, another lot in the hip and also on the tongue. When a sheep is found destroyed, place several lots of poison in the carcass. I have obtained as many as four foxes from one carcass in this manner. This method is very effective early in the season.

Foxes may be decoyed by means of a fox whistle and shot and hunted at night with a car or truck with a spotlight. Another method to prevent losses is to yard the sheep at night when the ewes are lambing.

To skin a fox, the easiest method is to skin like a rabbit, and open up the skin afterwards. It is advisable to peg out as soon as possible after skinning, as squarely as you can. Bury or burn all the carcasses of the fox; this will reduce blowflies and prevent cattle chewing the bones which may poison them. Again I make the plea that all farmers—whether they keep sheep or not—take united action early in the season to cope with this pest that is becoming an increasing and expensive nuisance in the mallee districts.

SOUTHERN CONFERENCE, STRATHALBYN.
August 16th.

FARM MANAGEMENT.

[A. H. Paterson, Strathalbyn.]

No one could hope to deal exhaustively, in a paper of this kind, with this subject. For successful farming the production of good crops and stock and the maintenance of soil fertility are fundamental. But more is required, for farming is a business, and business methods are as important as production methods. In a difficult period such as we are passing through, there is always a danger that we will lose heart and be content to muddle through. Granted that the difficulties of the farmer are very real, we should remember that depressions are not new; there was, on the average, a depression every 10 years during the last century, and there will be, unless the unexpected happens, depressions in the future; granted that the difficulties are very real, it is the man who is prepared to keep careful records and organise and cheapen production in every possible way who will eventually win the greatest success.

Business Methods.

A reluctance to keep records is a feature of farmers in general. Too often there is a failure to realise that nowadays farming has become a business. A generation ago a farmer was primarily a labourer. Physical strength and skill were his greatest assets. More is necessary nowadays. If crops and stock are produced at too great a cost and marketed unwisely a farmer may make very little headway. There must be a proper adjustment of capital, land, labour, and equipment. There should, for example, be no more land than the capital and equipment can handle to its full capacity. No more money should be invested in implements than can be used with profit on the land available.

A farmer should know thoroughly the market on which he has to compete, something about the regions in which his competitors work, and something about their methods.

The farmer of to-day has to farm land of much higher price than his predecessors —land which may have been depleted of its fertility by years of improvident farming. This lessening of fertility may have been masked by the better varieties

of plants grown and better manurial practices, &c., but in many cases must eventually show itself. More farmers fail because of faulty management than because of faulty production.

The principles underlying the raising of crops and stock do not alter, but the proper organisation of a farm may alter with every new invention. More farmers fail because the size of the farm or the methods employed do not keep men, horses, and machinery fully occupied than because of poor crops.

The kind of business ability needed is that required for the organisation of a farm into a successful business enterprise. An idle horse in the barn is a more frequent source of loss than is a bad bargain in buying a horse.

If the farm is large and requires a large amount of capital, the farmer should be capable of building up a good organisation and correlating the various branches of production. If the farm is small, the farmer must know how and when each section of the work should be done, and he must plan ahead and foresee most things liable to go wrong.

Bookkeeping.

How is a farmer to make a start to apply these ideas? A very simple system of bookkeeping will suffice. The first step is to draw up a balance-sheet. The balance-sheet consists of two columns—on the left liabilities, what the business owes; on the right assets, what the business owns. The excess of assets over liabilities represents the capital value of the business. Assets minus liabilities equals capital.

The capital value is placed under liabilities to balance the account. The drawing up of a balance-sheet involves the valuation of assets. Records should be kept from day to day of all transactions. It is sometimes difficult for the farmer to find sufficient time to attend to the books, so that it is preferable for some other member of the family to keep the records.

A receipts and payments account should be opened by entering the bank balance from the balance-sheet. From then on during the year all receipts and payments should be entered. A diary should be kept of all transactions in which payment is not made immediately. A valuable method of keeping check on one's books is to pay all money received into the bank and to make all payments by cheque. If this is done the bank pass book and the heel of the cheque book will be valuable records. Petty cash can be provided for by drawing a cheque in one's own favour as required. To separate various sections of the farm work, such as wheat, sheep, etc., a tabular receipts and payments book may be used.

At the end of the financial year, or at any time during it, a balance-sheet may be drawn up for the whole farm or for any section of it. By comparing the amounts shown as capital it is easy to see whether the business has progressed or not. Profit is an increase in the capital value of the business (including actual cash). It is not safe to think the increased bank balance is all profit.

To draw up a balance-sheet at any time, it is necessary to value all assets of the business, such as land, buildings, fences, stock, and plant. Depreciation in the value of assets must be allowed for according to their estimated life.

Any money withdrawn during the year for personal use should be added to the profits. A business which is in a healthy condition should return interest on the capital invested.

With such a simple system of bookkeeping in operation, a farmer knows just where he stands financially and, what is equally important, he knows how much each crop or sideline is helping or hindering the general position. Analysis of the records will also reveal important facts such as, for example, the cost of running a motor truck.

The keeping of financial records of each section of the farm business will point the way to further improvements. I refer to all that is included under the

heading "Production Recording." Any enthusiastic farmer will find such recording a fascinating interest. To know exactly the capabilities of each cow in the herd, or the result of a change in feeding or other management, is very valuable information.

PRODUCTION METHODS.

The production of good crops and stock and the maintenance of soil fertility are the foundations of good farming. A system of crop rotation should be adopted which will ensure the maximum production, consistent with keeping the soil in good heart. The effective utilisation of horse and man power depends very largely on having a suitable rotation.

I have been interested recently in the suggestion of a local retired farmer that an improvement could be effected in the usual rotation system by leaving pastures down for a longer period. This idea receives support in the June, 1934, Western Australian *Journal of Agriculture*. Western Australian experience has shown that with a rainfall of over 16in. the first Early or Dwalganup strain of Subterranean clover will establish itself quite satisfactorily. With less than a 16in. rainfall Burr trefoil and Cluster clover are the main pasture constituents.

Over 16in. rainfall the suggested rotation is:—Five years' pasture, crop, fallow, crop, fallow, crop. This would mean 500 acres pasture, 300 acres crop, 200 acres fallow on a 1,000-acre farm.

This division assumes units of 100-acre paddocks, in order that each year one paddock is changed from crop to pasture and one paddock from pasture to crop. Experiments have shown that better results are secured by grazing paddocks in rotation. If the area is fed off rapidly and the stock moved more often the pasture will yield much better. It is probable that twice as many sheep could be carried with 50-acre paddocks as with 200-acre paddocks.

For lighter rainfall areas, the basic rotation suggested is:—Four years' pasture, fallow, crop, fallow, crop, fallow, crop. This would mean 400 acres pasture, 300 acres fallow, 300 acres crop on a 1,000-acre farm. Modifications of these rotations may, of course, be made to suit individual requirements.

The chief advantage of these rotations is that much heavier pasture growth is obtained. The first year of a pasture would be very often more accurately described as a stubble period, and if the pasture is to be semi-permanent, it will repay extra expense. It is therefore suggested that the pasture should be top dressed annually with 50lbs. to 100lbs. of super and clover seed broadcast with the previous crop; or after the crop with the first winter rains, 2lbs. per acre of cleaned seed, free from burr, for Subterranean clover, and 1lb. for Burr clover or Cluster clover.

After a few years it should be possible to collect enough seed in burrs from the older-established pastures by raking during the summer. It will be necessary to cultivate Early Subterranean clover before raking to bring the seed to the surface. Collect seed from paddocks free from lucerne flea or red mite if possible.

The chief advantage of the rotation is the greater bulk of pasture obtained, which results in a greater amount of humus in the soil. Weed control and control of diseases and insect pests will also be much better.

The importance of legumes, such as clover or pease, in a rotation, cannot be over emphasised. These plants have the power of manufacturing the valuable plant food, nitrates, from the air.

The farmer must try to discover the point at which increased labour and fertility applied fail to yield a more than corresponding increase in crop return, and then endeavour to reach it but not pass it. A farm can be overworked, and the best crop that can be grown will probably not be the most profitable.

An aspect of farm management brought much before our notice by a year such as this is fodder conservation. Ensilage is a much-neglected method of storing fodder. It is fire, mouse, and weather proof, and is particularly valuable

when little greenfeed is available. The subject is exhaustively dealt with in a Departmental bulletin by Mr. Spafford. Other subjects which suggest themselves are weed and pest control, the handling of implements and machinery, construction of farm buildings, animal breeding and feeding.

In conclusion, the attitude of the successful farmer should be one of progressive conservatism. The progressive farmer will be ready to accept new ideas from any source, and, if they appeal to him, to test them out in practice. The ideas of agricultural scientists, agricultural journalists, business men, mechanics, and neighbouring farmers should receive due consideration. In any community where agriculture has been well established for some time the prevailing tendency of the majority of farmers is towards correct methods of cultivation. By carefully studying these methods it may be possible to make improvements. By a policy of progressive conservatism and a capacity for taking pains, there is the greatest chance that success will be achieved.

CARE AND MANAGEMENT OF THE POULTRY YARD.

[D. J. TURVEY, Milang.]

A survey of many farms indicates that one of the principal causes of impaired health and high mortality in poultry is due to inadequate housing. The farmer is inclined to keep increasing the number of his poultry and still crowd them into the same housing accommodation; over-crowding is a very dangerous practice, and often very unprofitable. I would rather have 100 well bred and well grown pullets than 200 that have been over crowded and insufficiently fed and cared for; it is not only eggs that we should look for, but we must realise that from these pullets we are to select breeding hens for future stock.

I have seen some farm fowls roosting in trees in all weathers, and their owners say that they do as well there as in a shed. It might do for a hen that only lays about 70 to 100 eggs a year; for such hens to be profitable their days are past, especially at the present prices of eggs, but with proper housing and feeding they are laying nearer 200 eggs a year. The official Victorian record is 337 eggs in 365 days; this should be convincing enough to see that fowls are given proper feeding and housing.

The farmer intending to build a poultry house should write to Mr. C. F. Anderson, Government Poultry Expert. I advise building his standard 100-bird house to start with, which is 20ft. long, 17 ft. wide, 7ft. 6in. high in the front, 6ft. high at back.

Having the ability to "pick the layers" is one of the prime essentials of successful poultry farming. The need for that particular ability arises when one is "mating up" for hatching operations, or when selecting laying pullets, or when the whole flock needs to be culled. Culling also plays an important part towards successful poultry farming.

First, look for the fowl with a good, smart, active appearance, moving about quickly—a fowl that appears to be constantly on the move, usually in search of food overlooked by her companions, or perhaps hunting for insects. Such a fowl is a worker that scatters the litter in a vigorous manner. The dull, inactive, slow moving and lazy hen is seldom a good layer.

Much guidance is obtainable from the head. Look for a strong beak, not too long and nicely curved, and bold, bright eyes. The comb should be of medium size and fine texture, wattles and ear lobes thin and smooth like a kid glove; head long, with inclination to be lean and narrow at back, and neck fairly long; the body should be long and deep with good width across the shoulders. The feathers should be close and tight-like in appearance. Fairly late and gradual moulters are generally the best layers. Quite a number of people now cull the hens solely

[*Papers Read at Conferences.*]

on the basis of those moulting by the end of January. However, this system may be somewhat drastic. On handling a laying hen the pelvis bones should be wide apart, the breast bone forced well down away from the pelvis bones, hence we get the scoring capacity of a hen from the distances apart these respective bones happen to be, the ideal distance being four fingers breadth between the two pelvis bones and five from the keel or breast-bone to the pelvis; these bones should be fine and not coarse. The quality of the skin is another indication, and heavy layers usually possess a skin with a soft, velvety texture.

The selection of the male bird for the breeding pen is of great importance; it is very hard to obtain all the desired points in a bird. The best idea is to get as many good qualities in the hen as possible, and then select a male bird who is strong in those points in which the hen is weak. If you mate two birds with the same faults then you will increase the faults. The influence of the male bird is most important in this regard. If you mate a bird with, say, 10 hens, each hen will be the mother of, roughly, one-tenth of the pullets, but the faults of the male bird will probably show through the whole number. Always be sure and select a male bird with good depth.

For egg production there are only two breeds I would consider—White Leghorns and Black Orpingtons, in that order of preference. On no account feed these two breeds together. The Black Orpington being a larger fowl needs more food, and the White Leghorn, being a more active bird, will pick up three grains to the other's two. If a farmer with the ordinary knowledge of poultry was given a large number of hens of each breed, he would find that he was able to keep the White Leghorns up to a high standard better than any other breed.

The feeding tests being carried out at Parafield prove conclusively that neither bran nor pollard is necessary in the composition of a good laying mash. No. 1 Test of crushed barley and crushed wheat and meat meal shows £3 13s. 9d. more profit than the No. 3 Test which consists of bran, pollard, and meat meal. These tests prove that we can carry on with poultry without having to purchase bran and pollard.

ALMOND GROWING.

[G. Sissons, Strathalbyn.]

The almond is a native of Persia, originally supposed to be a poisonous plant growing wild, that has since been improved by cultivation. There are two sorts of almonds, the bitter and the sweet; the sweet is the variety grown in this country, the bitter is grown in the south of Europe and North Africa for the extraction of its oil which is used medicinally and in the manufacture of flavouring essences.

So far as Australia is concerned, South Australia is the home of the almond. In most parts of the other States, except for a few varieties, the almond sets its fruit very sparingly, so that its cultivation appears to be a profitable industry here for some time to come. In the past the tree has been sadly neglected, being mostly used as a breakwind, the nuts just planted and left to take care of themselves; possibly the cause for this has been the cost of labour for harvesting, but since the introduction of machinery for hulling and cracking the nuts, the almond is now coming into its own. There is still, however, the need for a reasonably priced cracking machine to suit the needs of the small grower. Grown for commercial purposes, the almond is usually budded on peach or almond seedlings. Perhaps the most reliable way of getting the variety one needs is to grow and bud one's own seedlings, being sure to use buds from well-established proved bearers. On the whole, it is a better proposition to procure the young trees from a reliable nurseryman and save the loss of one or perhaps two seasons. Before deciding on the varieties to plant, I advise a canvass of the district to find out what sorts

suit the locality. When selecting a site, a well-drained position, free from frosts, and away from growing timber, should be aimed at; if grown near timber I advise planting hard shells. The cultivation of the land should be as thorough as for any other orchard tree, deep-ploughing in the first place with plenty of after-working. The trees should be planted not less than 25ft. x 20ft. apart but 30ft. x 20ft would be a better proposition.

They should be cut back hard for the first two seasons and kept pruned for 4 or 5 years. If spring and summer pruning can be done, it will save a lot of cutting and conserve the energy of the tree. With upright growers like Brandis, the centre should be cut out and the remainder pruned to outgrowing buds. The spreading varieties need to be cut back to in or side buds for several years, making the branches go upwards, permitting close-up cultivation, also the twigs should be thinned out occasionally, preventing the tree becoming too bushy and preserving the identity of the main limbs. These branches or secondary arms must be given plenty of room and not be so numerous as they can be in the Brandis. Old trees whose wood is becoming exhausted from bearing should be renewed by cutting back branches to the secondary arms, extending the operation over three or four years.

Eleven years ago I planted 400 trees, and at the start made two serious blunders —one was planting too closely, so that now I have to grub a third of the trees in one block; the other was relying on the descriptions given in a catalogue instead of finding out what sorts suited my locality. The varieties I planted were:—Brandis, Ne Plus Ultra, Imperial, Commercial, I.X.L., White Nonpariel, and Jordan (hard shell). Of these, I have had the best results from Brandis, I.X.L., and Imperial—the Brandis being the best weighers and most consistent bearers. Ne Plus Ultra has been the most prolific, but failing a wet summer it is almost impossible to hull them, so most of them have been cut down and budded to Chellaston and Johnston's Prolific. Commercials were no good. They were cut down and budded afresh. White Nonpariels were the worst bearers of all, although they flowered profusely every year; they were cut down and re-budded. The hardshells suffered the same fate for the same reason.

Seven years back I planted 135 Chellaston, and so far they promise to be my most profitable investment; the nut has rather a poor appearance, but they are the best of weighers, and have a good, plump kernel. Three years ago I budded Stockholm's on White Nonpariel stumps; last year there was a nice sprinkling of nuts, and this year a good crop. They produce a fine, large kernel, but the shell is easily torn. Seven years ago I budded Johnstone's on Ne Plus Ultra stumps; they have borne good crops, but this year did not open well. I think they need more moist conditions.

As an experiment Johnston's were budded on prune stumps two years ago last summer. The buds have grown well, and with the exception of one tree there was no gumming. They bore a few nuts last season, and are now covered with blossom.

HILLS CONFERENCE, COROMANDEL VALLEY, AUGUST 23rd, 1934.

GREEN PEACH APHIS (*Myzus persicae Sulz*) AND ITS CONTROL.

[By R. FOWLER, Manager Blackwood Orchard.]

The first severe infestation of Green Peach Aphis occurred in 1924, and a second in 1928 at the State Expermiental Orchard, and, I think, in South Australia generally. Up to that time, though present occasionally in small numbers, it had not been responsible for any severe losses, nor had any efforts been made to learn anything of its life history or means of control.

[*Papers Read at Conferences.*]

After the outbreak in 1924 it became apparent that this pest's potentiality for doing damage and causing loss to peach growers was tremendous, and that steps would have to be taken to discover, if possible, some effective means of control. The ordinary methods of combating aphis, used with success against black aphis, were tried against the green aphis in 1924, without success, and we then turned our attention to winter washes, and all subsequent trials have been with egg killing spray materials.

From our experience and observations since the first epidemic in 1924, it is apparent that a general outbreak of green aphis in great numbers occurs at irregular periods of three or four years, when considerable damage to the peach and nectarine trees results, with a serious loss of crop; and in the years when not in plague numbers, sufficient damage has usually been done to warrant the application of a winter spray; so that the position has now been reached when it would appear to be uneconomic not to apply a winter spray as an insurance against loss by green aphis.

A great deal of experimental work has been done since the outbreak in 1924, and the life history of the green aphis has received considerable attention since then, particularly by Mr. K. M. Ward, of the Victorian Department of Agriculture, who recently published in the Victorian *Journal* the results of some years of research work. At the present time three problems still confront the grower, and research work is still needed to determine whether—

(1) It is possible to forecast severe outbreaks of green aphis by studying climatological records, and observing the numbers of migratory females that return to the peach trees in the autumn, and the numbers of eggs to be found on the peach laterals.

(2) Is it possible to achieve complete control of green aphis by means of ovicidal or egg-killing spray materials?

(3) To determine the most efficient of these winter spraying materials, and the most economical ones to use.

Life History of the Green Aphis.

Some confusion still exists in the minds of growers as to the manner in which the various species of aphis—black and green of the peach, black of the cherry, and woolly aphis of the apple—hibernate during winter and re-infest the trees in spring. Without a proper knowledge of the life history of these insects at this period of the year it is impossible to deal with them intelligently.

The life history of the green aphis under Australian conditions has now been thoroughly investigated by Mr. Ward, and much useful detail has been obtained; but previous to this in South Australia Dr. Davidson, of the Waite Institute, had determined, from material supplied from the Experimental Orchard, that the migratory females returned from the summer host plants to the peach trees in May, and that eggs were to be found on the laterals in June and July; so that it is known that this species does deposit eggs on the trees during the winter, and that egg-destroying winter sprays might be used with some chance of success.

The life cycle of the green aphis may be briefly stated as follows:—Eggs are deposited during late autumn, singly, mostly on the 1-year-old laterals, the eggs being placed in the axils of the buds or in crevices of the bark. The eggs are at first light green in colour, changing to a shiny black in three or four days and hatch during midwinter and early spring giving rise to the stem mothers. These feed at first on unopened buds and develop into the adult stage slowly. These forms are apterous, *i.e.*, wingless ,viviparous, *i.e.*, produce living young and being parthenogenetic, they do not require fertilization by the male of the species. Their progeny are wingless and develop more quickly than the previous generation.

They feed on the blossoms, opening leaf buds, very young fruits and leaves, and it is the swarming of this generation which causes the early curling and distortion of the leaves, so characteristic of the early spring injury. Later, when growth on the peach and nectarines has further developed, a third generation appears which feeds on the leaves and shoots. In this generation alate or winged migrants begin to appear, and in later generations increasing numbers of migrants are produced until all adult aphids are winged.

A complete change now occurs in the feeding habits of the insect. It leaves the primary or woody host and commences to feed on secondary host plants, which are herbaceous, such as Cape weed, marshmallows, and garden plants, weeds, &c., and their progeny carries on the life cycle of the species on the secondary food plants.

During April and May the return migratory forms begin to appear on the peach trees, and close observation will reveal the winged female, with a colony of eight to ten young round her, generally on the upper surface of the leaf and near the midrib. It is thought that the autumn migratory flights are probably over short distances only, as it is noticeable that the outside rows of a block of peaches generally carry more of these migratory forms than the inside and more eggs are generally found on trees near the headlands than on those further away.

The small colony of 8 or 10 young produced by the autumn migratory forms consists of oviparous or egg-laying females. They are not green in colour, but rather a shade of red and brown, somewhat the colour of the laterals or leaves on which they feed. These sexual females are fertilized by the migratory males which come from the summer host plants. The egg-laying female may lay from 7 to 13 eggs over a period of 20 days. The stem mother may produce up to 60 living young. The third and fourth generations mature more quickly than the first and second, and produce about the same number of living young.

This life history information is based on K. M. Ward's studies, and our observations in the Experimental Orchard, where this pest has been under observation for some years. In Victoria—and I think the same would apply in South Australia—Mr. Ward found that the duration of periods of activity was as follows:—

Autumn migration—April 20th to May 30th.
Autumn generation on peach—April 20th to June 18th.
Oviposition—May 5th to June 16th.
Hatching—June 28th to August 23rd.
Destructive period—June 28th to December 4th.
Over-summering period—December 4th to April 20th.

In the above Table it will be noted that eggs are laid between May 5th and June 16th. This has an important bearing on the time the winter spray should be applied. To get the best results it is necessary to wait until the last migratory female has returned to the peach trees and has finished laying her eggs. Apparently this could be towards the end of June, so that any time after that would be an effective time to apply the spray. During a normal winter, when the weather is usually wet and boisterous in July, it might be possible to get the spraying done before the ground becomes too saturated with water, making it almost impossible to get the spray pump over it.

The damage done by the green aphis to the peach tree is twofold. The stem mothers, when they emerge from the eggs, commence to feed shortly after hatching, and draw their food supply from the leaf and flower buds. This must inevitably interfere with the normal development of the bud. By the time the blossom buds are opening many of the first generation have been born, and these attack the various parts of the flower, resulting frequently in its destruction, and

no doubt the killing of many flowers results in a lighter crop being produced. After the blossoms the aphid attacks the young leaves which are just forming, and when in plague numbers the effect of their presence is seen in the curled-up condition of the leaves. As a result the young laterals, which should bear next season's crop, become stunted and distorted, and so weakened that they are not in a condition to bear fruit; so that the crop immediately following the plague year is also more or less affected by the previous season's infestation.

In 1924 and 1928, both plague years, in many instances the upper portions of some trees were so badly injured by the attacks of green aphis that many of the leaders died out, and not only was the new season's growth distorted but the actual framework of the tree itself was more or less destroyed.

Growers will have to study their own conditions to some extent, because all peach orchards do not suffer to the same degree, even in a plague year, and in the off years some may suffer badly while others escape altogether. Again, some orchards may be subject to attack almost every spring. What determines the severity of the infestation in these cases it is hard to determine. Probably one factor is the proximity and abundance of the summer host plants.

Control Measures Adopted.

Our first experiments were carried out in the winter of 1925, after the severe outbreak in 1924. We then used red oil, black leaf 40 and soap, and lime sulphur. These tests were repeated in 1926, but there was only a slight infestation in that year. Lulled into a sense of false security, we did not put out any winter sprays in 1927 and 1928, and as a result were badly hit in the latter year. After the infestation occurred we tried black leaf 40 and soap, red oil and soap, black leaf 40, and nicotine dusts, but with very little success. In the winter of 1929 we again used red oil, white oil, Kleenup, rustica salus, and lime sulphur. In 1930 we repeated most of the 1929 programme, and included Mortegg and Cooper's tar distillates. There was rather a bad infestation of green aphis that year.

In 1931 and 1932, owing to extremely wet winters, no winter spraying was possible. Again we tried to control the green aphis with spring sprays and by using white oil mixed with Burgundy curl-leaf spray, but did not get satisfactory results. Tests were also made with other proprietary lines mixed with Burgundy, but no satisfactory results could be claimed.

Results of Experiments.

From observations made after these tests were carried out it was evident that if the aphides were allowed to reach the stage when the leaves became curled and distorted then it was almost impossible to reach all the insects with a contact spray, and repeated attempts to do so would prove costly and uneconomic. The only solution seemed to be the winter sprays. Of those used, speaking in general terms, the most effective have been the tar distillates. The oil sprays applied in the autumn proved fairly effective, but not absolutely efficient. The oil sprays, however, seem to have a general beneficial effect on the trees themselves. Experience has taught us that the time sulphur, black leaf 40, and nicotine dusts in these experiments were applied too early. These materials would probably have given better results if used when the buds were just unfolding in early spring.

In 1933 we again put out a number of winter washes, and in order to get a more tangible idea of the results, made a count of all the laterals affected by green peach aphis on the sprayed and check trees, assuming that the sprays had failed to destroy the eggs on these particular laterals.

TABLE I.—*Data in Connection with Green Aphis Spraying Experiment in Variety Block B. Record taken* 26-10-1933.

Date of Application.	Plot.	No. of Trees in Test	Spray Material Used	No. of Trees Examined.	No. of Trees showing affected Laterals.	No. of affected Laterals.
9/6/33	1	40	[illegible]	20	2	10
	2	40	Tar distillate Coopers 1-35.	20	5	14
	3	40	Gargoyle Red Oil, 1-25	20	6	43
	4	40	Destructol Emulsion, 1-35.	20	6	21
	5	40	Not sprayed, check rows .	20	12	63
	6	40	Kleenup, 1-35 .... }	20	6	16
		40	Lime Sulphur, 1-35 .... }

20/6/33	8	40	Shell Red Spray, 1-20 .. .	20	5	13
10/7/33	9	40	Cooper's Ovicide, 1-40 ..	20	—	—

Trees unpruned when sprayed.

TABLE II.—*Data in Connection with Green Aphis Spraying Experiments in Elberta Block. Record taken* 25-10-1933, *and in Variety Block L* 27-10 1933.

Date of Application.	Plot.	No. of Trees in Test.	Spray Material Used.	No. of Trees Examined.	No. of Trees showing affected Laterals.	No. of affected Laterals.
20/6/33	A	12	Mortegg, 1-35............	12	3	8
10/7/33	B	12	Mortegg, 1-35............	12	—	—
10/7/33	C	12	Check row	12	9	46
			Variety Block L.			
10/7/33	D	18 }	Cooper's Ovicide	10	2	3
			Check row	6	6	110
17/7/33	E	18 }	I.C.I. Winter Wash No. 1 (6galls.-100)	10	—	—
			Check row	6	5	152
	F	18	I.C.I. Winter Wash No. 2 (6galls.-100)	10	—	—
			Check row	6	6	198

The figures show that the tar distillates gave almost 100 per cent. control, and the winter oils, though varying a little, gave some measure of control as compared with the check rows. Spraying was done at various times during winter, June 9th and 20th and July 10th and 17th, and the later applications gave slightly better results than the earlier applications.

The Imperial Chemical Industries Ltd. washes are made up on what is known as the East Malling formulae, and gave good results, as seen from the figures. At the time these observations and counts were made it seemed possible that the green aphis might increase rapidly, but the winged forms developed and then disappeared, and soon sprayed and unsprayed trees looked alike.

We have again applied another series of test sprays this winter, but it is too early to report on them yet, except to draw attention to the following Table, which shows the results of some examinations made by Dr. Davidson, of the Waite Institute, on the number of eggs to be found on laterals taken from trees sprayed with various egg-killing spray materials. The figures do not indicate very much, except that, in spite of the numbers of migratory females noticed in the autumn, comparatively few eggs were laid, but it must be remembered the length of wood examined is very small when compared with the total lateral growth on the tree. Most of the eggs were found on rows 15 to 18, these being next to the outer boundary headland.

[*Papers Read at Conferences.*]

TABLE III.—*Aphis Observations.*

Treatment.	No. of Shoots Examined.	Total Length of Shoots.	Eggs Whole Apparently Healthy.	Eggs Hatched or Damaged.	Young Aphides.
		feet.			
A. Rows 9-12	26	33	4	3	0
B. Rows 13-14	26	31	2	0	0
C. Rows 15-18	24	27	30	5	0
D. Rows 5-8	23	27	4	0	0
E. Rows 1-4	25	26	9	3	0

A. Sprayed Shellicide D 1 20 Nicotine Sulphate 1 in 800 on 25/6/1934.
B. Not sprayed.
C. Sprayed Gargoyle Red Oil 1 25 on 2/7/1934
D. Sprayed Crude Petroleum 1 20 on 25/6/1934
E. Sprayed Ovicide 1-35 on 25/6/1934.

Judging by the numbers of migratory females observed in the autumn, and reports of the egg counts from other districts, it is rather feared that next season may be a bad one for green aphis, and the Department deemed it advisable to issue a warning to that effect through the press and 5CL, which we hope reached most of those concerned.

TAR DISTILLATE SPRAYS.

Following on the more general use of tar distillate sprays, one or two questions have arisen:—

(1) The probable cumulative effect of tar distillate washes on the tree if applied year after year.

(2) Will any damage result if a frost follows soon after the application of tar distillate?

(1) So far no permanent injury is noticeable. Certainly there is some discoloration on the 1-year-old laterals after tar distillate sprays, but the injury, if any, appears to be only on the surface, and does not affect the subsequent growth or fruit bearing of the laterals. As most of these laterals are shortened back or removed when pruning the following season it is hard to see how any permanent injury can result.

(2) I have not heard or read of any injury through frost after using tar distillate. Our weather records show that on several occasions severe frosts followed the applications, but no injury resulted.

SUMMARY.

The question of forecasting outbreaks of green aphis is under consideration at the Waite Institute, but more data is needed before any predictions can be made.

It would seem that tar distillate will give almost perfect control of green aphis, and that it is the most efficient and economical spray material to use for controlling green aphis.

That it should be used strictly as a dormant spray, at a strength of 1-35 or 40, applied before the middle of July.

That winter oils have not proved as efficient as tar distillates.

That black leaf 40 and soap, if used, should be applied later than tar distillates.

That it is almost impossible to control green aphis with contact sprays after it becomes well established in the spring.

Considerable work has been done at the Experimental Orchard in an endeavour to find out the most efficient method of controlling green aphis, which threatens severe damage to peach orchards in the State.

[*Papers Read at Conferences.*]

That green aphis eggs are laid mostly on the laterals, and so therefore considerable numbers will be destroyed if the peach and nectarine prunings are carefully picked up and burnt.

It should be remembered also that tar distillate sprays have a burning effect on the skin, and the operator should take all precautions to protect himself and also the horse drawing the outfit. So far as the operator himself is concerned, he should protect his face and hands with either castor oil or some petroleum grease, and endeavour to carry out the spraying in such a way that as little as possible of the spray will drift over him. He will not, for instance, attempt to spray against the wind.

Trees may be sprayed before being pruned, but less spray will be used and a more effective job done if the trees are pruned before being treated.

ORCHARD DRAINAGE.

[By MAX J. VICKERS, Lenswood.]

This is a subject I feel very strongly about and one, I might say, I have never heard discussed at a Bureau meeting.

What mainly prompted me to attempt this paper was the realisation of the many mistakes I have made during the last 15 years and the possibility of other growers being equally unaware of the right methods of drainage. I am assuming, of course, that the method which I am now advocating is correct.

IMPORTANCE OF DRAINAGE.

In the Lenswood district, with a heavy rainfall and usually wet conditions in early spring, drainage is more than ordinarily beneficial. Of all drainage, subsoil drainage is, of course, the most necessary for orchards, particularly throughout our district, where, in many instances, even in comparatively short rows, there are three distinct types of soil frequently met with. Ironstone gravel on the top half, gradually merging into a brown loam, and finally into a stiff grey soil, or pipe clay, at the bottom of the slopes.

Water drains through the gravel, as through a sieve, but meets with resistance in the tighter soils, which forces it to the surface. The surface conditions which go to show the need of drainage are obvious and easily noted. Most stiff clayey soils require drainage and give tremendously increased results when so treated, added to which they are much easier to work when drained, and remain in condition longer, after being cultivated, without setting or forming into lumps or clods.

Indications.—Any flat or low-lying piece of ground on which the water lies for any length of time after rain "will not give much reward to the one who tills it until he tiles it also" is an adage I once read.

Soils upon which rushes, water grasses, ti-trees, &c., grow can be classed safely as soils which must be drained to get the best results.

Any piece of land you contemplate draining you will be wise to closely observe, during the wettest period of the year, in order to get a guide for the actual position of the drains, as frequently certain oozy, boggy patches, hard pans, &c., occur in unexpected places.

Systems and Types.—Many orchards in Victoria have a tile drain between every row of trees. While this system allows for the job being done piecemeal, a cheaper and better system is to plan out the drainage scheme before the orchard is planted and have the main drains further apart, with lateral drains of smaller dimensions at frequent intervals.

No drain should be longer than 400ft. without an enlargement of the size toward the outlet, that is, when using 2in. or 3in. pipes.

There are various types of drains in use. Many people have far more open surface drains in their orchards than allow for convenient working. Underground drains are in use made with brush; also slabs, placed crosswise on a ledge with a channel underneath; also split timber or poles placed longwise. Then th re are stone drains, and lastly mole-drains made by a recently devised mole-plough. These may be a success in this district with its pugnacious clay subsoil and freedom from sand patches which tend to cave in.

None of these are so thorough, long lasting, and efficacious as tile drains, however, and when the amount of labour entailed in laying them is costed up, are they so cheap?

Distinction of Conditions.—In relation to drainage there are two classes of water or moisture to be considered—that of hydrostatic water, and water or moisture that results from capillary action. The forces that give these two results are diametrically opposed in their action.

Without capillary attraction we would have no moisture left in our cultivated soils after the dry season sets in.

"Capillary attraction is best illustrated by the fact that we can half fill a bucket of water, and by putting in a strip of rag with one end resting in the water and the other reaching out over the top of the bucket, it will soon be found the water will drip from the end hanging outside the bucket. Briefly stated, it is the power of the water to rise through some agent and remain above the level of its source. Thus, we have an illustration of the wise provision of Nature, which provides moisture for all plant growth from the water stored down in the subsoil during the wet season." (I quote this from McHarg Bros. Tile Pipe Makers, Hobart.)

Another illustration I might give is, when we water a pot plant of, say the Gloxinia variety, by pouring the water into the saucer in which it stands, it is then drawn upwards by capillary attraction through the soil.

Hydrostatic water is that which is forced up to the level of its source, but is not able to rise any higher. Thus, if we dig a hole anywhere in wet ground during the wet season, it will fill with water to the exact level to which the surrounding country is saturated. Soil that is full of hydrostatic water will not grow anything.

Now we come to the reason why underground drainage gives the best results. If surface furrows or drains are used, these allow the fertility of the soil to be washed out; this particularly applies where bonedust and chemical manures are used.

By removing the surplus water down through the soil it not only prevents loss of fertility, which results from the wash, but actually adds it in the shape of one of the most potent forms of plant growth, nitrogen, which the rains bring down from the atmosphere. As this filters through the soil it is arrested and held by the soil particles and thus made available for plant food.

Subsoil drainage, it has been found, has the effect of keeping the ground warmer during the winter and early spring, thus encouraging earlier growth, also enabling one to get on the ground and plant earlier.

It has been found, too, that crops on well drained soil are not nearly so liable to frost injury as those on undrained ground.

Effects of Evaporation.—One of the reasons why undrained heavy soil is slower of growth early in spring is that there is so much water near the surface, which mostly has to be evaporated by the sun's rays before the ground can be warmed. Evaporation has a most chilling effect on the soil's surface or, for that matter, on any wet surface. Why do we fill a water bag and wet the outside? So that the water will become cool. This is brought about by evaporation from the surface of the bag, while the porous nature of the canvas allows it to continue.

[*Papers Read at Conferences.*]

Who has not experienced the feeling, when, after coming out from a swim, if the wind is blowing, one immediately becomes freezing cold. This is the effect of evaporation. Exactly the same thing happens with a saturated soil in early spring.

Drains act Horizontally, not Vertically.—If we drain our orchard we increase the depth of it, and thereby we increase the size of it. An agricultural drainage engineer of Missouri State Farm said:—"I drained my farm whilst in debt in order to get out of debt."

A common idea of the action of drains is that they draw the water directly down from above them. This is not so and is undesirable into the bargain. They draw horizontally. I know of persons who have ploughed an open furrow directly above the drains up the centre of the three rows to assist them. This is wrong practice and might result in their getting blocked with sediment. If you take notice of freshly cut banks of soil, you will see practically all soil or rock strata run horizontally and not up and down. The same thing applies to water saturation which really follows the openings between these layers.

All well sinkers, &c., know this. We know also that the pumps on different mine workings have lowered the water levels for miles around in various parts of the world. This is proof enough of the horizontal action of drains and of water through the soil; in fact, if it were not for this feature underground draining would be of little value. What we require of a tiled drain is that is draws from either side as far as possible.

If convenient, say, at a fence or headland, it is a good idea to have an upright pipe for an air hole in a long line. Immediately on this being provided it will be found that the pipe line, which may have been working sluggishly before, will instantly empty about three times the volume of water. This plan is particularly desirable where a pipe line empties into a creek or drain in which the level of the water may be a foot or two above the level of the outlet pipe.

Effective Position of Drains.—Much controversy takes place on where the pipes should be laid. Many advocate they should follow down the steepest slope, arguing that water drains down to the lowest level by the shortest available route, and that the suction of this action would pull the water out of the pipes laid across the slops or diagonally.

I, however, favour laying them across a slope just above the level where the water rises to the top soil. I find the land above, being freer, will drain itself, whilst my pipes catch the water as it comes down and carry it off, preventing it soaking in the low-lying land below, therefore effectively draining that.

No water-loving trees such as willows or poplars must be allowed to grow near drains. Their roots will force their way through the smallest opening and eventually clog the drain.

Methods of Installing Tiles.—In laying the pipes the ends should be quite close, in fact, touching. The suction draws the water through these intersections more effectively, it is said, than if they are left a quarter of an inch apart, leaving less chance for sediment to enter and clog.

I have held and outgrown a number of ideas during the last 20 odd years that we have been using tiles on which is the best way to cover them. At one time we carted ti-tree or brush and laid on top of the pipes before filling in. Then for years we used to cover them with 2in. or 3in. of a soft, shelly, flakey, slate-stone (of which there is a quarry in the middle of the place) to make the surroundings porous.

Then, after asking growers in various States and in other countries their methods, I find quite a good idea is to throw in the stiffest clay first and stamp it down, although possibly it pays to lay a strip of bark first on top of the pipes—a plentiful article in these parts—to prevent the entry of any foreign matter for the first winter while a re-setting or settling is taking place.

[*Papers Read at Conferences.*]

The action of tile drains has been found, after careful observation and experiments, to consist of taking the water in from the sides and underneath, and this is the action that we desire. The upper end of the drain should be blocked by a flat stone.

Conclusion.—In the foregoing I have endeavoured to give some of the reasons why we should drain, and of the benefits to be derived from it; and of the latter there is no room for argument in the negative, except that some will say it is an expensive job, but it if is going to permanently increase the productivity of our orchards it is well worth while. It will surely allow thousands of those anaemic-looking little rose-bush type of trees to grow into vigorous, 10-bushel, average ones.

Tile drains always appeal to me as faithful things Frequently, when going home at night in the wet season I have stopped and listened to the bubbling of the water from one of them, and thanked God something did not limit its hours of labour, but worked while others slept.

THE CARE OF THE LAMBING FLOCK.

[A. W. Robinson, Gumeracha.]

During the gestation period which is from 140 to 147 days (in the ewe) as with all pregnant animals, the main food needed by the ewe is proteins and mineral salts in order to meet the body formation and requirements of the young lamb. Ewes deprived of proteins will rob their own body systems to supply the needs of the young lambs. The result of this is unhealthy lambing, dead lambs, loss of ewes at lambing, poor milk supply in ewes, and consequently malnutrition or loss of lambs before weaning. During the gestation period and after lambing a daily ration of about two linseed sheep nuts—linseed cake broken into nut form—to breeding ewes increases lambing percentages, makes lambs stronger constitutionally, and better able to withstand marking and attacks of disease, enhances the milk flow in ewes, and also aids wool growth.

Percentage of Lambing.—Our lambing figures do not compare favourably with those of Great Britain, where the average sheep farmer expects at least 100 per cent., and often reaches 150 per cent., while many of the flocks average 120 per cent. year after year. These figures are the more striking when we compare our weather conditions with those of England. Our season is in mild or warm weather, while that of Great Britain is about freezing point. The English methods entail much more labour than is generally necessary with Australian flocks:—

1. The English-bred ewe is more prolific, therefore we should endeavour to breed crossbred ewes to get best results.
2. The English farmer is more particular in the use of sufficient rams, and more readily rejects old and stale rams.
3. He arranges shelter for lambing ewes, and has a shepherd in constant attendance. This shows that certain precautions are necessary to avoid needless losses.

Care of the Ewe.—Ewes should be handled with great care. Do not allow badly bred or badly trained dogs to rush about the sheep. A good, quiet dog will help to quieten the sheep, and should be trained to work well out from the flock. Any rough animal should not be used. It is a good plan, if possible, to arrange for a field near the homestead for the lambing paddock. The paddock should be well grassed with native pasture for preference, well drained, and clean and dry under foot. If possible, windbreaks should be in existence. Plant trees on the windward side of the paddock and, in fact, all the stock paddocks should have breaks for the comfort of the stock generally. Usually it is adviasble to divide the flock before lambing, picking the ewes that are likely to lamb early. The picking of sheep heavy in lamb can usually be done by feeling the udders of the

ewes. At the same time great care should be taken not to roughly handle the ewe when doing this. Under our own conditions it is not usual to have a man specially engaged for the care of the lambing ewe, nor is it absolutely necessary. With the paddocks as close as possible to the homestead, and the services of a good hack, one man can attend to 500 ewes in about three hours, providing the weather is mild. He should go round the flock twice a day, keeping a sharp lookout for ewes that are about to lamb It is not wise to interfere too early, as Nature will right itself, and damage is often done by interfering. It is wiser to leave a ewe and return to her an hour or so later. If assistance is needed it should be done with great care. The normal presentation is the forefeet, followed by the nose, and with this little difficulty is experienced. Often, however, presentation is at fault, and then difficulty arises. Should any great difficulty be encountered, the lamb should be gently pushed back into the womb, turned round, thus correcting position, and then, as in normal cases, proceed to draw the lamb gently downwards and outwards. It is a cruel procedure to attempt to draw a wrongly presented lamb, and should, therefore, be avoided. Nature provides plenty of room for the turning of the lamb in the womb, and hence little difficulty will be encountered if this is done Experience will teach a man thoroughly. Cleanliness must be observed, and it is a good plan to anoint the ewe with carbolic oil. If a ewe will not take a lamb a good plan is to tie her up, or pen her in a small yard with the lamb—perhaps the ewe will have to be held for the lamb to have a drink. Another good plan which has proved successful is to smear the lamb with the ewe's milk, and also smear the ewe's nose with her own milk to which a little bran has been added. A motherless lamb may be placed on a ewe which has lost her own lamb by adopting the above method.

During rough weather it is advisable to carry a small bottle of olive oil or brandy. Often a little olive oil will revive a weak lamb. Bringing a lamb into a warm room will often revive it. Should the ewe be lost it is a good plan to thoroughly wash the lamb in a bath of a temperature of about 103 decrees, and thoroughly dry and wrap in a warm covering. As the lamb does not get the "colostrum" milk of the ewe, the nearest approach is cow's milk, half pint fed through bottle and teat. Add to the cow's milk one teaspoonful of sugar and the white of an egg per day to supply the extra albumen that is in the colostrum milk of the ewe. Lambing pens have been found useful in wet districts. A yard 1 chain square is enough for from 200 to 300 ewes. This yard should contain a small haystack where the ewes will be able to nibble and also keep themselves dry under foot. This shelter should prove useful on the farm for other stock during the part of the year when not used for lambing. Lambing pens also encourage ewes to feed from troughs. This should be necessary.

Tailing.—This should be done when lambs are young. It is not advisable to wait until all the lambs have been dropped, especially if the lambing is a protracted one. The best age is about two weeks The knife is the quickest and easiest, and the stump heals more quickly than after the searing iron. There is some risk, however, of the lamb bleeding to death. Much bleeding can be prevented if the lambs are tailed in cool weather, and the flock should be rested both before and after tailing. The searing iron stops bleeding almost entirely. It has a tendency to cause a scab, and does not heal so quickly as with the knife. The iron, should be kept at an even heat; a white-hot iron will often injure a bone with fatal results. Lambs should be done young. Another method is to cut with the knife and sear the main artery with the iron. This stops bleeding without forming a scab. Earmarking should be done at the same time as tailing, and every farm should have a distinctive earmark. Ewes and lambs should be pastured on some prepared crop of either rape or barley. It is advisable to change the paddocks as often as possible; *i.e.*, daily, instead of once a week. A good plan is to let sheep feed on

ordinary ration through the night and morning, and turn on to, say, rape in the afternoon. This allows them to gain much more feeding value. Care should be exercised in the detection of scouring if such should occur. Concentrates such as crushed barley or oats are helpful. If a lamb is to be sold at 4 to 4½ months it is much better to sell direct from the mother. If the object is to sell a 50lbs. to 60lbs. lamb, which means holding the lamb for six months, then weaning is probably the better method.

CONFERENCE AT YEELANNA, EYRE'S PENINSULA BRANCHES, September 5th.

SEED WHEAT.

[R. R. WILSON, Yeelanna.]

Conference at Yeelanna, Eyre's Peninsula Branches, September 5th.

The wheat grower cannot pay too much attention to the character and quality of the seed which he uses if he desires to secure the best results. It is not sufficient to sow a good-yielding wheat and neglect the quality. Both are of great importance to growers, who should select a wheat possessing quality as well as yield. Ford is one of the most suitable for this district, and this variety is also a very fair hay wheat if there is a better demand for hay than grain.

It is often said that shrivelled grain is the best for seed, because there are a larger number of seeds per bushel, and lighter seeding would be required. This is wrong; we should regard seed wheat in the same way as breeders of livestock look upon their animals. Do not sell the best, but retain it because the grower hopes to produce equal to it, or improve upon it. It is worth while to keep back double the requirements for seed, run it through the grader, and market the rejected half; then carefully grade the seed again before sowing. Then the seed will be of uniform size, and only the largest of the grain sown.

It is also often stated that two-year-old wheat is preferred to one year. This is hard to understand because, although a grain of wheat is capable of retaining its germinating powers for a long time, still as every year goes by a certain percentage of the grain dies and loses its germinating power. Always regard grain of the preceding harvest as being infinitely superior to older grain, and use no other for seed purposes There is every advantage in grading seed by eliminating small, shrivelled, and broken grain. Broken grain may be useless; it may contain no germ or, if the germ be attached to it, it will not be able to supply the young plant with all that is needed for the early stages of its development. On the other hand, the elimination of the small and shrivelled grain is also an advantage, because:—

1. The germinating power of the large seed is invariably greater than that of the small seed of the same variety.
2. Under similar conditions the large seed invariably gives rise to higher yields both of grain and straw than small seeds.
3. The percentage of large grain in wheat raised from large seed is always greater than when small seed is used.
4. The weight per bushel of wheat grown exclusively from large seed is invariably greater than that of wheat raised from small seed.

The effect of grading and sowing only the large seed is to ensure a more perfect and regular germination; hardier, healthier, and more evenly-developed plants; heavier yields both of grain and straw, and a heavier sample of wheat.

There is a strong opinion with some farmers that wheat grown on the same land tends to degenerate, and that it is a good policy to obtain seed from another district or neighbouring farm. It is probable in some cases that the degeneration

is due to neglect of selection and the manner in which the seed has been handled, by getting it mixed with other varieties through not cleaning out machinery when going on to another variety. However, if a change of seed is needed choose it from a cooler district if possible, as it matures earlier the first year.

The quantity of seed per acre varies considerably in some cases, and the question is governed by a number of factors:—

1. The climate of the district, because a wet district needs thicker sowing than a dry district.

2. It may depend on what the crop is required for; a hay crop needs to be sown much thicker than a grain crop.

3. It will vary with the character of the wheat; free stooling wheat can be sown 10lbs. or more less than those which do not stool so freely.

4. Late seeding needs much thicker sowing than early.

5. If a growth of weeds is anticipated sow thicker.

6. If the land is in good condition with a compact seedbed to ensure good germination sow thinner. Seventy pounds to 80lbs. appears to be a suitable dressing for this district; 90lbs. if land is dirty; 90lbs. to 100lbs. for a hay crop, as a thick crop of hay usually produces hay of better quality.

New land need not be dressed with the amounts mentioned; 50lbs. of graded seed is sufficient for new land, and it needs to be sown early.

Much credit is due to the inventor of the separator which is embodied in the present-day grader. It has been the means of practically getting rid of the objectionable Cape Barley in seed wheat.

BETTER WHEAT-MARKETING METHODS.

[E. A. Pfeiffer, Cummins.]

When a survey is made of the methods under which some of our secondary productions are marketed overseas, such as the trade in barley, butter, eggs, frozen meat, and other commodities, one cannot fail to realise the decided advantage of the schemes under which these commodities are traded.

Take, for example, the butter trade, in which a system of grades is in operation, and under which countries such as Denmark have established a wonderful reputation for their products. Butter being one of the chief exportable commodities of that country, Denmark has striven, not only to obtain a certain standard, but the highest degree of quality that it is possible to obtain, with the consequent result of its enviable reputation. If, therefore, other countries who aim at the highest quality of their chief exportable products can obtain such pleasing results, it is undoubtedly also possible that we in Australia can achieve similar results with similar marketing methods. It is only necessary to investigate the position of the wheat industry of the world in general, and of Australia in particular, to see the deplorable conditions with which this, one of our chief exportable commodities, is faced. Let us therefore ask ourselves what is the best means whereby this most valuable industry can be re-organised, and again made profitable?

From time to time various schemes have been put before the wheatgrowers, but have had the disadvantage of requiring some boosting, which naturally means that revenue from other sources has to be utilised to bring such schemes into operation. While wheatgrowers would momentarily benefit by such schemes, they would ultimately have to forfeit such benefits by being burdened with increased taxation.

The present marketing method of our wheat is carried out on a f.a.q. basis, a standard to which the wheatgrower is required to come up to if he wishes to receive the ruling market price for his product. This standard of quality does not induce the grower to produce wheat above a certain standard, consequently the enthusiastic grower who could produce a superior quality wheat to that which is classed as f.a.q. does not do so because he has the knowledge that he would not receive any more than the ruling market price for such wheat.

[*Papers Read at Conferences.*]

THE ADVANTAGES OF SELLING BY GRADES.

If, however, a system of grading were brought into operation whereby a grower's wheat could be classed into, say, three or four different grades, with a distinct price for each grade, wheatgrowers could be induced to produce the highest possible quality of wheat in the world, which would have a very beneficial effect to our country. Just as the Danish butter is preferred to any other in the world by overseas buyers because of its outstanding qualities, just so would Australian wheat be preferred by overseas millers. If, therefore, all wheat produced by Australia was of the highest possible quality, then such wheat would be preferred to wheat of other countries, and millers would naturally be prepared to pay a better price. If the overseas millers paid more, then overseas buyers would also be in a position to give a better price when they bought the wheat from the Australian merchants, who in turn would be able to pay the grower more for his products.

The natural result would be that wheat growing would once again become profitable. These grades would be determined by the milling quality of the grain itself, freedom from foreign matter such as smut and other diseases, and absence of weed seeds which have a tendency to leave tainted flavours when the wheat is milled.

The varieties of wheat grown under this scheme would play the most important part, for millers decidedly prefer those varieties which contain the highest percentage of gluten, for this content is very essential from a baker's point of view. Only a very limited quantity of low gluten content wheat is actually required. Perhaps the only use to which this class of wheat can be put to advantage is in the manufacture of biscuits, where a flour is required which does not "rise" to any appreciable extent.

Canada, America, and Argentine, on account of atmospheric conditions peculiar to those countries, can produce wheat with a remarkably high gluten content. Consequently if Australians do not make an effort to produce wheat of high gluten content then we are faced with the danger of having to lose otherwise favourable trade conditions. Types of wheat such as Pusa are excellent milling wheats, both on account of the hardness of grain and high gluten content, and would, therefore, under a system of graded marketing, be ranked among the highest grade of wheat. Naturally such wheat would also receive the highest price. If then, a farmer exclusively grew these types, and concentrated to produce the highest quality grain, free from diseases and taints, such a farmer would be the one who would receive the greatest income from his labours. However, if some farmers were to continue to grow types of wheat which were not very suitable for milling such as Free Gallipoli then they would, unless good market prices existed, not receive sufficient reward for their labours, for such types would be classed as a much lower grade, and would, therefore, receive a decidedly lower market price.

There are doubtless some farmers who would view this with prejudice, for they hold that wheats such as these yield better, grow denser straw, will not lodge or shake, and have other advantages from a grower's point of view. But that is where an advantage of this scheme would come in, for the fact that wheats of the best milling type are as a rule not good yielders, would have to some extent the effect of reducing over production. The only means of encouragement to farmers to grow good quality wheat to-day is offered by the Royal Agricultural Society and country shows. But apart from the wheat exhibited it does not require the farmer who is enthusiastic enough to display such exhibits to produce all his wheat of that quality. Then there are the Crop Competitions conducted in various parts of our wheatgrowing communities. It cannot be contradicted that schemes such as these are invaluable to progressive wheatgrowers. Undoubtedly the aims of these schemes and those of a system of graded marketing are identical for they all aim at better quality.

The only difference between these schemes is, while Crop Competitions, Show Exhibits, &c., are only beneficially effective to a section of the community, a system of graded marketing would be of national advantage. Barley has been marketed under this method, and has been found highly satisfactory. This system has helped barley to maintain a fair price while wheat prices slumped. The writer does not here wish to infer that had this scheme been in operation prices would not have slumped, but it is reasonable to assume that better prices would have ruled had such methods of marketing been in operation.

The fact that quite a number of wheats grown in Australia are of poor milling quality is beyond argument. And unless some scheme is brought into existence whereby buyers can rely on Australian wheat being superior and consistent in quality our reputation as a wheatgrowing country will vanish. It is, then, possible that Australian wheat will be branded as "inferior," and cause the world's wheat buyers to turn towards other markets.

STABILIZING THE WHEAT INDUSTRY.

[G. A. Vigar, Mount Hope.]

The most urgent question before the Australian public to-day is the rehabilitation of the wheatgrower. It is one of the three leading occupations of rural Australia—wheat, wool, and cattle raising. Probably it gives more employment than any other industry, for it is far-reaching in its effect. Every secondary industry reflects almost immediately the financial position of the wheatgrower; if the wheatgrower is prosperous a market is immediately provided, and probably the best market for all the secondary industries.

[*Papers Read at Conferences.*]

The Commonwealth Government to-day is endeavouring to make arrangements to insure the wheatgrower getting a better return for his labour next harvest, and it is one of the functions of this Conference to advise the Commonwealth Government the best plan to adopt. The plan I suggest is an Australian price for all wheat and flour of 4s. per bushel, and a bounty sufficient to bring a return of 3s. 4d. to the grower at all sidings and outports where wheat is shipped overseas.

Also the erection of grading plants at all deep-sea ports, so that only first-grade sample wheat be shipped overseas, the second grade wheat being sold as such for poultry and cattle feed. The erection of the above grading works would give employment to many men when unemployment is greatest, and at the same time secure a better price for all wheat shipped overseas The wheat-grower must adopt the same principles as the fruitgrower, and only send the best out to the world markets. The question of financing the above scheme would not be difficult, judging by the buoyancy of the Commonwealth revenue through good prices for wool, the buying power of prosperous farmers would provide sufficient revenue (in a country taxed as high as we are in Australia) to cover the tax to pay the bounty on all wheat sold overseas. The operation of the above scheme could be carried out by the present wheat buyers acting under a board of control appointed by the Federal Government, and the scheme would only last until world prices rose in order not to need any Government assistance.

The wheatgrower has every right to ask the rest of the community to come to his assistance while wheat prices are low, as the policy of Australia is a highly protective one, and the wheatgrower up to date has been penalised by it.

SOME ASPECTS OF MORTALITY AMONG SHEEP FROM EATING STINKWORT.

[M. T. Gardner, Koppio.]

Although it is said to be 70 years ago since stinkwort first made its appearance in South Australia in the Onkaparinga district, it is only 30 years ago that the writer first came to have any experience in mortality among sheep from the effects of eating stinkwort. Just prior to finding sheep dead in paddocks in numbers to suggest unnatural deaths, several sheep died in a neighbour's paddock which were considerd to be due to the effects of eating freely of well-grown gum shoots around trees which had been rung previously, and the same results can happen (deaths) in stinkworth infested paddocks if sheep are turned in in the right stages to affect them. Uninitiated sheep owners who have had no experience with stinkwort can easily be trapped by a mistake in this direction, and find to their sorrow in a very little while they have suddenly acquired experience of a very costly nature without any warning or chance to recoup the losses sustained.

Those who have had the experience of losing valuable sheep in varied numbers often thought they were taking precautions to ensure a supply of feed in autumn and saved a stubble paddock for sheep—perhaps for ewes lambing early—and up grew the stinkwort in the dry stubble. Towards the end of April or early in May the sheep were turned on to the paddock, and at the time of the year when dewy nights and misty mornings are frequent the sheep were found dead. It was from such experiences that information concerning stinkwort mortality was obtained, and now by taking precautions sheep can be successfully kept on stinkwort country without losses occurring.

How Stinkwort Affects Sheep.

Usually stinkwort grows better on cultivated land, and sheep usually graze on land which has been most liberally treated with phosphatic fertilisers. Toward the middle of autumn the stinkwort comes to the end of the growing period which

is the setting of seed pods, and this occurs with the period of the year when the best of the summer fodder is about cleaned up and most greenfeed gone. Then, often sheep are grazing on pastures of poor nutritive value, and consequently eat a lot of fibrous material of rather an indigestible nature which by passing through the stomach causes irritation of the intestinal organs. This may go on for a fortnight or three weeks without the owner noticing much amiss with the sheep except that a few show signs of scouring and are not thriving. Others have a brownish, slimy discharge, and when the seed pods are taken into the stomach with dew or mist dead sheep are noticed lying about. After one has had experience with sheep affected with stinkwort it is possible to detect odd sheep which will die later when being moved or driven, the same refusing to travel and looking thin and hollow. These are often sheep that have been kept out of stinkwort paddocks and then allowed to graze where this weed is growing, and if it so happens that the seed pods have dried to the fatal stage—when the seed pod has lost its yellow flower and the end of the pod has turned brown, with the pod just openings and the seed spikelets inside being in a state of rigidness, and with a dewy night or misty morning—then mortality often occurs in large numbers in a single night. There appears to be some action like the piercing of the intestines by the seed spikelets which sets up an irritant poison and causes the death of the sheep feeding on the stinkwort seed. The water in dew or mist seems to accentuate death after the seed pods have beeen consumed, at a certain stage of dryness. We know what action water has on drying seeds of the geranium plant and the wild oat, and possibly the moisture causes some mechanical gyrations of the stinkwort seeds in a similar manner.

How to Avoid Deaths and still keep on Stinkwort-affected Holdings.

This may be a more important phase of the subject than how sheep are affected, and it requires some care on the part of the flockmaster where all fields are covered with stinkwort or some in every paddock. It cannot be all eaten down at once in the early stages. When eaten with the good stubble feed sheep get a lot of feed off it when it is young. If one had enough sheep to do this all the other feed would soon be gone, too. Where sheep are kept on stinkwort they eat most of it before the seeds form, and there is not enough left to do them any harm, but it is while the grazing is going on on that portion that the trouble is storing up in other fields, and it is those fields that have water and are reasonably easy of access that one must graze out sufficiently for the sheep to live in without fear of loss, whilst the other fields are shut up waiting for the danger to pass, which is usually about a month's duration. This year I shifted sheep on April 20th and replaced them in the stinkwort field on May 23rd without any loss.

If the food in the grazed area is short, some provision must be made to replace same. It is no use saving sheep from stinkwort to let them starve to death or to weakness unable to resist death from the rigours of winter. A variety of ways can be used to feed sheep during isolation. Oats or barley can be tipped out on the ground, provided there is roughage enough left in the paddock, at the rate of ½lb. per sheep per day, or chaff fed in self-feeders at the rate of 1lb. per sheep per day, but this entails a lot of labour to feed a large flock.

Pregnant ewes must be fed sufficiently to keep them strong and in good condition to rear lambs. Another way to provide fodder is to have some paddocks of lucerne, which has been proved will grow well on Lower Eyre's Peninsula. This is best planted in spring on well-prepared land. This fodder grows well in early winter, and in a season like the present would be several inches high by the end of April.

For those keeping sheep on Lower Eyre's Peninsula it appears to be necessary to provide dry feed for young sheep during April and May, and if this were the practice the stinkwort menace should not trouble us much so far as the young

sheep are concerned. The strong, dry sheep could fare more hardily than any others, and ewes would be the only extra to be fed provided some run without stinkwort was available for the dry sheep.

Sheep would be grazed away from such fields where danger of mortality abounded, and the feeding would have a three-fold advantage—saving the sheep, cutting more wool, and saving the feed when the danger period was over. Better lambs would also result, and those aiming at fat lamb production would benefit.

The dry feed fed during isolation from danger would not be wasted, as the remainder of paddock feed would be saved; this in turn would provide more feed during winter, and better nourished sheep cutting more wool would be the result.

CARE OF FARM MACHINERY.

[W. E. Bryant, Cummins.]

A very considerable amount of the cost of production of farm products can be reduced by taking reasonable care of implements, machinery, and plant required on the average farm. Unfortunately we often see costly implements put under trees for fowls to roost on, or left out in the paddock or in the open yards, exposed to all weathers, which very quickly reduces their value and usefulness, and also increases the cost of their upkeep. Much of this could be avoided with very little expense by making use of the material close to hand and providing covering for them.

We probably all like stone sheds with iron roofs, or failing that iron sheds, with or without iron sides, as finance permits. Unfortunately the cost of either of the above type of sheds is very often beyond the farmer's means. A very cheap and effective shed can be made from straw and bush timber, which is usually available at a low cost. A shed 60ft. long by 30ft. wide can be erected with 18 forks, or failing all forks, use half forks and the balance straight poles. Twelve forks or poles 10ft. 6in. to 11ft. long would be required for the sides, six on each side. The other six for the centre should be at least 6ft. longer to give the roof a good slope or fall; if they can be secured longer they will be much better. All uprights should be placed at least 2ft. 6in. in the ground.

After placing the wall-plates and ridge-poles in position, place the rafters on them about 4ft. apart; have rafters long enough to go over the bottom wall-plates at least 3ft. (rafters should 19ft. to 20ft. long). I suggest boring a ½in. hole through the small end of all rafters, and tie each rafter to the one on the opposite side of the shed with double fencing wire. This prevents them slipping down. When tying rafters to the bottom wall-plates do not bore them. The battens should be placed about 2ft. apart, and either tied or nailed down to the rafters. This, if covered with broom brush and straight straw, makes a cool and fairly waterproof roof.

The straw should be cut and tied with a binder; use straw that has been stripped if available; it is much better than straw that has been cut by headers or reaper-threshers. The straw should be thoroughly soaked with water and then placed on the shed as wet as possible; this makes the straw pack together very closely. All sheaves should have the bands cut and removed. Start covering from the bottom the same as for thatching. The bottom row of straw should be tied to the lowest batten with string of twine—hay bands will do. Place all the other straw straight and carefully on the roof about 6in. thick As the roof is completed, tie 10-gauge fencing wire to the rafter at one end, and hang a weight on the other end of the wire; this keeps the wires tight at all times, as expansion or contraction does not affect it. Allowing the roof to go 3ft. or more over the side of the shed gives good shelter without side walls.

In this type of shed all implements and machines or vehicles must be taken in and out at the ends, but this is not difficult where one has horses or a tractor. By using a little discretion when putting implements in the shed much time and inconvenience can be saved when the different implements are required. I suggest putting the waggons, drays, lorries, or similar vehicles in one side of the shed, and the harvesters, binders, combines, &c., that should be under cover on the opposite side. While the risk of loss from fire in this class of shed is greater than where stone or iron sheds are used, it is much less than the loss incurred from depreciation in both efficiency and value when implements, &c., are left out exposed to the weather, and the latter loss is very certain.

Another considerable saving can be effected by keeping all bolts, nuts, and screws tight, and when replacing worn or broken bolts using one of the correct size. When putting implements away it is a good practice to clean all oil, dirt, and grease from them. This can be done very easily while it is soft, but if left on until it becomes hard and dry it is far more difficult to remove, and takes more time to do and is an unsatisfactory job when it is finished. When cleaning the implements, a note should be made of all badly worn or broken parts, and these should be replaced before the implement is required for use again, and not left until the last minute to do so.

TOMATO GROWING IN THE OPEN FOR CUMMINS AND YEELANNA DISTRICT.

[R. GRANIT, Cummins.]

The tomato ripens at the time of year when the farmer is compelled to work long hours in excessive heat, and there is hardly any other dish which is looked for with greater desire than is the tomato when due to the heat hot meals have to be replaced by cold meals consisting partly of fruit of some kind. Not only does the tomato provide a desired food at the time of ripening, but the housewife may store supplies for later date by preparing some of the tomatoes for sauce, pickles, jam, &c., and besides providing the desired food, it also gives to the housewife that personal satisfaction which is accompanied with all home industry. The object of this paper is to induce every farmer to grow sufficient for his own requirements. The following method which is recommended for the above districts may also be adopted in other districts where the soil and climatic conditions are similar.

Preparation of the Land.—It naturally follows that a quick-maturing plant such as the tomato should always be planted in ground which has been prepared some considerable time prior to planting, so that the required plant foods are available as soon as the seedlings are planted out. The land should be turned over three months or more before planting, and kept free from weeds.

Plant Foods.—The writer's observations have proved that most growers dig farmyard manure into the ground at the time of planting out the seedlings. Owing to the time required for the rotting process, and until it has become available plant food, best results are not obtained from such practice, and the writer recommends a liberal dressing of superphosphate at the time of first turning the ground, as it will then be readily available for the seedlings when planted. Should burned lime be available a dressing of same would prove beneficial.

Seedlings.—Due to the sensitiveness of the tomato plant to extreme conditions, and to gain satisfactory results, all check to the plants should be safeguarded, and

this can best be done by rearing the seedlings on the farm. The usual practice of placing fresh stable manure into the bottom of the seed box, although assuring a good germination of the seed, should not be practised for the following reasons:—To avoid any severe check to the plants the seedlings should be hardened as soon as possible, and the writer starts the hardening from the two-leaf stage by removing the glass from the seed boxes during the day, but owing to the strong westerly and south-westerly winds experienced during spring it is often necessary to keep the glass on the box for several days without removing same. Should the bottom of the box be packed with manure it would provide excessive heat during those days when the seed boxes remain covered, with the result that the seedlings become soft, and when opened will receive a check with undesirable results. Where a watered, heated seed box is available it would be an advantage.

The seed should be sown in boxes during the early part of August, and the seedlings are then ready by the end of September, when the reappearance of frost is unlikely. The seedlings should be planted in rows east and west, 2ft. 6in. apart and 3ft. between plants, and protected from wind for some days after planting.

Pruning and Training.—The plants should be pruned by removing any side shoots that are sprouting, and the writer has had best results by pruning the plant to one single stem in its early life, and later allowing one or more to appear. In many instances growers are in the habit of driving one or more stakes into the ground, and then allowing the plants to climb the stakes vertically. The best results cannot be had from the above practice because:—(1) The vertical flow of sap retards the fruit-bearing habit of the plant, and (2) the plants are subject to the strong winds which often destroy the flowers.

To encourage the fruit-bearing habit of the tomato plant its growth should be trained horizontally as soon as possible, and it is usually done by having a trellis erected, but as the trellis requires material and labour, especially when it should be removed annually to fresh ground, very few go to the trouble of having a trellis erected.

A number of years ago the writer experimented with the following method of training the plants, which proved such a success that he is confident in recommending same to others The method is as follows:—By cutting No. 10 galvanized fencing wire into lengths of 15in. and bending 3in. of one end to a loop. As soon as the plant has reached the height of 8in. the wire is pushed into the ground with the loop over the plant, forcing the plant to bend over. The plant should be trained towards the east because (1) of its natural tendency to go towards the morning sun; (2) because of the prevailing westerly winds in spring the training will be easier if directed towards the east.

As soon as the plants have made further growth the wire should be pulled out and placed further on the plant to keep same growing horizontally, also having a steadying effect on the plant. This must be repeated constantly during the growing periods. At the end of the season the wires should be collected and stored for the next year.

Watering.—The district having a clay subsoil, care should also be used in waterin the plants, as excessive watering is applied in most cases. Of course the weather is always a big factor, and should be taken into consideration, but during summer when no rain has fallen a good watering once in every 10 or 14 days will give the best results.

Disease Control.—Remove all affected fruit from the growing area and thereby prevent undesirable spores from entering the earth.

SIDELINES ON THE FARM.

[MESSRS. LAWRIE BROS., Ungarra.]

Mixed farming under present conditions appears to be essential on this part of the Coast. Neither wheat, wool, dairying, pig raising, or poultry, &c., when conducted only as a farm for any one of these products, seems to produce the necessary income to cover the expenses of production and provide a reasonable living for the farmer. Marketing conditions do not appear to be suitable for poultry raising as the sole source of income, but when conducted in conjunction with other lines it is quite a different matter. Considering these sidelines under separate headings I will enumerate some of the methods which we have more or less successfully adopted:—

Wheat.—We have cropped fair acreages, and the yield has been up to average, but the price too low to make the sale of all the wheat as such profitable, so we decided to divert part of the good and all the inferior wheat to more profitable use. To do this we considered pig and poultry raising.

Wool.—Prior to last season the previous years' prices have not been high, and we only handle small flocks of sheep. The work entailed in handling fills in the slack part of the year, and produces a substantial cheque and also the ration sheep.

Dairying.—This is one of the best of the sidelines, as it produces an income throughout the whole year. Dividing it into sections, the first consideration is:—

(*a*) *Pasture.*—We recommend dividing the paddocks into the smallest practical area, because cows relish a change of paddock, and with small paddocks frequent changes are possible.

(*b*) *Grass.*—Natural green grass contains most of the elements necessary to produce health and milk fats from the cattle. The Dairy Council have provided seed and super for experimental plots on our property of Wimmera rye grass, Subterranean clover, and lucerne. Rye grass is very forward, and the stock are doing well on it. Lucerne and Subterranean clover should provide good summer greenfeed, and it is our intention to fence off a portion of the lucerne, and irrigate it in summer.

We have been advised that lucerne, if given to the cows either fresh or cut, or by allowing them to graze on the growing crop, is likely to give the milk a rank flavour and also to do harm to the cows; the better was is to cut the lucerne and allow it to stand for at least eight hours before feeding.

The natural grasses on the farm are barley grass and silver and spear grass, and these are only good for a couple of months, drying off at the first signs of summer, consequently it is vitally necessary to supplement them with more lasting species.

Top Dressing.—We have adopted this in a small way, and results prove that further extensions are advisable. Last season we used 45 per cent. super and about 120lbs. to the acre, the land which has been topped dressed showing much better and more lasting growth than the ordinary paddocks.

Breed.—The climate and class of country bears a big influence on the breed of cattle to be selected for the farm. The climate in these districts is not severe, and is very suitable for the Jersey. The breed to be selected is a matter for long experience of local conditions, and we consider that it is advisable when starting out, for a farmer to take the advice of those who have been successful in the particular district to be operated in, or better still the experts provided for that purpose by the Government.

It is not always possible for a farmer to start off with a good herd of high-class cattle, but it is within his power to gradually improve his herd. It is essential that the bull come from a proved milk fat producing strain. Butter factories have provided the means for a farmer to test his cows, and by having the cows tested monthly the production for the whole period of the lactation can be known.

By fattening those cows whose production is less than 250lbs. of butterfat for the year and selling to the butchers, a farmer in a few years can, by breeding only from those animals who have proved their value, soon have a herd which are money producers and not simply work producing cattle.

Housing.—A cow produces milk from the surplus value of the food she eats beyond what is required for her own existence. If no shelter is provided, it necessarily follows that the colder the animal is the more of the food is used to generate her own warmth. A few good trees in the paddock or better still a fair-sized straw stack provide protection from the elements which help milk production.

The milking sheds should be clean and on raised ground, the floor well drained and, if possible, of concrete. Stalls should be provided, and each cow regularly milked in the same stall and in the same order. The manure heap to be some distance from the milk yards. The separator room should be detached from the shed and on the opposite side of the shed to that from which the usual winds blow. We have found a decided reduction in the work of the house by having a roofed passage way between the cow sheds and the separator room, and in this the cleansing of the utensils is done.

Feed.—As previously pointed out green grass is the finest food cattle can have, but the cows are more contented at milking time if fed on a little dry chaff with crushed oats added. In cold weather and during the period of dry feed we give the cows an addition to the chaff of crushed oats and a little bran and linseed meal, but consider that the crushed oats show much better results in our cream cheque than the bran.

Milking.—Regularity of time of milking is very important, and so far as possible have the same person milking the same cow each day Contentment of the cow has a big influence on her production, and the cows get used to a person and seem to give better results if the same person always milks them.

Pigs.—This sideline has its importance in the profitable use of pinched grain and skim milk, and by raising pigs we receive almost as much value from the skim milk as we do from the butterfat.

Housing.—We have provided sties of stone, roofed with thatch and intend flooring with concrete and bedding with straw, for farrowing and topping off for market. The growing pigs and weaners we are running in small green feed paddocks.

Breed.—Acting on recommendations from the bacon factory we are using Large White boars and Tamworth-Berkshire sows and averaging five litters in two years.

Feed.—Before farrowing, we feed the dry sows on soaked oats. After farrowing the sow receives pollard, crushed wheat and crushed barley mixed with skim milk and cut green feed, placing a portion of the same food in a dish outside the sty, but accessible to the young pigs through a space below the bottom rail of the sty. Weaners have similar foods and when topping up for market the pigs are fed on all dry foods, crushed wheat and barley and meat meal, with the addition of clean skim milk. It is our endeavour to have the pigs fit for curing within five months of farrowing. Clean sties produce healthy pigs.

Poultry.—The export trade has not been of any benefit to the Coast as yet, because merchants state they cannot receive sufficient quantities of the class of egg required to make the cost of testing under export conditions profitable owing to the methods of transport fracturing the air cells. With conditions as they exist, we have to make the best use of the facilities available, and so have concentrated on raising birds capable of producing the most eggs and also birds for show purposes. White Leghorn and Black Orpington have proved the best breeds for laying, and we do not favour cross breeding with poultry. The sidelines on our farm have borne results quite the equal of any other branch of our operations, and that, even with the low prices available, when properly conducted, a farm can be successfully run to-day when the true methods of mixed farming are adopted.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on September 26th, 1934, there being present Messrs. A. J. Cooke (Chairman), A. M. Dawkins, J. W. Sandford, F. Coleman, H. N. Wicks, A. J. A. Koch, and H. C. Pritchard (Secretary). Apologies were received from Messrs. P. J. Baily, G. Jeffrey, Professor A. J. Perkins, and Dr. A. E. V. Richardson.

Congress.—The Secretary reported that arrangements were well in hand for this year's Congress.

New Branches.—Approval was given for the formation of Women's Branches at Wirrabara, Sheoak Log, Monarto South, and Wilmington, with the following Foundation Members:—*Wirrabara*: Mesdames N. Keynes, L. C. Menz, H. J. Watt, G. and C. Kranz, C. Cooper, H. Banfield, E. and H. Curtis, E. Frances, W. Noblet, B. Holland, J. Porter, and Miss J. Menz. *Sheoak Log*: Mesdames M. Eden, A. Noll, D. Hienjus, H. and E. Dahlitz, G. Bamman, A. Sissman, D. Everett, V. Bowden, M. Geue, H. Koch, T. Mitchell, E. Tremlett, E. Lienert, H. Argent, Misses E. and H. Tremlett, K. and H. Koch, F. Kuhlmann, D. Matthews, M. Everett, C. and E. Sissman, J. Argent, Z. and K. Bamman, V. Dahlitz, L. Noll, B. and D. Eden. *Monarto South*: Mesdames H. B. and C. White, C. F. Altmann, F. Liebelt, E. Hartman, E. Schnoars, T. Bretag, V. McAdam, Misses G. Strauss, M. Hartmann, F. Aesche, E. Hein, V. Baum, J. Cottrell, and S. Schenscher. *Wilmington*: Mesdames S. Genders, H. Stevens, M. Christophersen, J. Drennan, M., P., and J. Modystach, J., A., and J. Hampel, G. Stoney, P. Cole, Haase, A. Pitt, H. Duhring, Bury, Pengelly, McGhee, L. Wright, Davidson, Misses M., F., A., E., K., and T. Modystach.

Life Members.—Life Membership of the Agricultural Bureau was conferred upon Messrs. J. G. Pearce (Milang), E. H. Schulze (Taplan), and H. Jacobs (Cherry Gardens).

New Members.—The following New Members were approved:—Hope Forest and Dingabledinga Women's—Miss E. DeCaux, Mrs. R. Wade, Mrs. L. DeCaux; Butler—A. and H. Parker; Caliph—J. W. Burnett; Wirrilla Women's—Mrs. T. Jacka; Laura Bay Women's—Mrs. A. H. Barnett, Miss D. Blumson; Pygery Women's—Mrs. M. and Miss M. Kammerman, Mrs. C. Gosling; Truro—Jas. Miller; Watervale—Mr. J. W. Baillie; Truro—Rev. W. Catterall; Sutherlands—W. Doecke; Echunga—C. J. B. Symon, E. T. Oinn, P. T. Duffield, A. W. Cobbledick, C. Witcke, W. G. Colebatch, E. A. Liebelt; Snowtown—J. F. Kelly, M. Freebairn; Wilmington Women's—Mrs. - Brown, Mrs. - Clark, Mrs. H. Noll; Wilmington, L. W. Harvey; Mount Gambier—John Livingstone; Penola Women's—Mrs. R. H. Ricketts, Mrs. A. Balnaves, Mrs. E. P. Walsh, Mrs. C. Rickard, Miss G. McWaters, Miss J. Neilson, Mrs. R. McDonald; Belalie Women's—Mrs. P. W. Frost, Mrs. J. Pilkington, Mrs. W. Glasson; Moorlands—A. R. Payne; Dudley—E. Possingham, E. Jamieson; Arthurton—R. W., A., and H. Burns, P. and L. G. Ford, J. R. and R. Fergusson, P. G. Kitto; Rosedale—M. Eve; Blackwood—C. H. Eglinton; Penwortham—W. K. Birks, A. L. Wayman; Hartley—A. A. Hutson, N. J. Cross; Boor's Plains—Frank Reid; Warramboo Women's—Mrs. F. E. Swanson; Inman Valley—W. A. and S. Hacklin, H. Hagger, J. B. Rogers, J. Astbery, T. E. Bear, R. H. Hagger, W. R. Beresford; Wudinna—J. W. L. Shillabeer, W. M. Smith, W. M. Bartley, R. L. Naylor, H. J. Bartley; Roberts and Verran—R. D. Jonas; Pinbong—J. D. Roberts; Goode Women's—Misses T. and I. Paech; Goode—E. M. Goldsmith; Hartley—A. Wundersitz, A. Brook, R. H. Cross, A. E. Jaensch; Light's Pass—A. H. McLay, H. C. Reade, J. A. Craig, J. A. Tscharke; Bute—G. A. Green; Lenswood and Forest Range—J. Martin, A. Cramond; Kalangadoo Women's—Mrs. J.

Rogers; Chilpuddie Rock—R. Redding, F. H. and H. J. Pearce, H. A. Cant, J. W. Parsons; Greenock—C. and H. Werner; Goode Women's—Mrs. R. A. Lange; Warcowie—B. E. and E. G. Telfer; Koolunga—E. Fuller; Marama—D. Rawlings; Parilla Women's—Miss J. Carman, Misses H. and V. Edward, Miss D. Phillis; Coomandook—L. McArdle, R. Williams, K. Wilson, J. Martin, J. Gulley, P. C. and R. Crouch; Auburn Women's—Mrs. S. Stephens, Mrs. B. Burfield, Mrs. D. Garrett, Mrs. Brokenshire, Mrs. Bert Allen; Nunjikompita—C. May, R. Dunn, H. E. Pascoe, J. Dolling, S. B. Lang, B. Salmon; Rendelsham—R. Lane, K. Stuckey; Balaklava—G. Whiting, T. Harvey; Clare Women's—Mrs. F. K. Knappstein, Mrs. J. W. Berryman, Mrs. E. Catford; Ki Ki—W. O. Cooley, H. Goodall, R. Owen, G. E. Wyatt; Palabie—Roy Mullins, T. Silvy; Brownlow—B. Schutz; Morchard Women's—Miss F. Brown; Penola—A. A. Green; Wasleys Women's—Mrs. J. Mullins (senior), Mrs. J. Mullins (junior); Pinnaroo Women's—Mrs. W. Wilson, Mrs. J. E. Hannigan, Mrs. B. I. C. Vianeldo, Miss L. Badman, Miss F. Davis, Misses J. and N. Mattiske, Miss E. Atze; Owen—K. Wilson, A. Freebairn, M. Saint, H. Bradley; Calca—J. Harris; Roseworthy—W. J. Alters, A. J. Riggs, A. Pengilly, J. O'Brien; Milang—R. J. Newland; Taplan Women's—Mrs. S. and Miss D. Grant, Miss E. Hammond, Miss E. Condon, Mrs. G. and Misses D. and K. Schwerdt; Yurgo—W. Skelton, E. W. and E. H. Kriewaldt; Aldinga—C. Bird, S. C. Payne; Wilmington—I. G. Schulz; Currency Creek—W. Langham; Cungena—M. A. Quinn; McLaren Flat Women's—Miss E. Air; Kybybolite—G. J. Webster, W. D. Starick; Pinnaroo Women's—Mrs. E. T. Eichele; Paskeville—J. Tiddy; Mundalla—J. Humphreys, J. Sabey.

Present No. of Members, 7,384; present No. of Branches, 335.

Several items were discussed in Committee.

DAIRY AND FARM PRODUCE MARKETS.

Messrs. A. W. SANDFORD & CO., LIMITED, reported on October 2nd, 1934.

BUTTER.—Production throughout September increased fairly rapidly as good general rains were received in most parts of the State and the feed came along nicely. Unfortunately, the London market has gone from bad to worse, and although stocks on hand have been somewhat relieved, there were still about three-quarters of a million boxes of New Zealand and Australian butter in cold stores in Great Britain at the end of the month. London values were down to 66s. to 67s. per cwt. for cold stored, and 1s. or 2s. per cwt. higher for fresh landed. Local prices also eased, but with the Voluntary Plan, which was being operated by the manufacturers, the position of the farmers was materially helped. Choicest creamery fresh butter in bulk, 1s. 0¼d. per lb.; prints and delivery extra. (These prices are subject to stabilisation levies.) Store and collectors' lots, 5d to 5½d. per lb. according to quality.

CHEESE.—Manufacturing is in full swing at present in the South-Eastern factories, and a number of them are working almost up to capacity, as the rains in the Mount Gambier district have fallen at the right time and the pastures are better there than in other parts of the State. Exporting of the surplus continues, and local and Western Australian trade was well maintained. Large medium, 8¼d. to 8¾d. per lb.; loaf, 8¾d. to 9¼d. per lb.; semi-matured and matured, 8½d. to 9d. per lb.

EGGS.—Since our last report quantities have increased rapidly and merchants have exported all that would pass the graders. With the local trade and pulp manufacturers putting down quantities for winter use, markets were kept nicely cleared, but, generally speaking, production is lower, although prices are higher in consequence than for the corresponding period last year. Ordinary country eggs, fair average quality, 7¼d. per dozen net; export quality, clean eggs, 1¾ozs. and over, up to 10½d. per dozen net.

BACON.—Ample supplies were marketed throughout the month by the factories, but trade was well maintained, especially for middle cuts and boneless rolls. Hams for current trade were purchased in only limited quantities, but some booking for Christmas hams were recorded. Prices were firmer, and it is expected that higher rates will rule for hams as the Christmas season approaches. Best quality sides, 9¼d. to 9½d. per lb.; middles, 10d. to 10½d.; rolls, 8d. to 8½d.; hams, 11½d. to 1s.; cooked, 1s. 1½d. to 1s. 2d per lb.; lard prints, 5d. per lb.

ALMONDS.—Good clearances were effected from week to week, although the supplies were not very heavy, as many of the growers have ere this fairly reduced stocks. As the date of report the demand seemed likely to continue and sellers are advised to consign. Softshells and Brandis, 9d. to 9¼d. per lb.; hardshells, 5½d. to 6d. per lb.; kernels, 1s. 11d. to 2s. per lb

HONEY.—The quality of the consignments received were, generally speaking, of a high standard, but buyers only purchased sparingly and interstate trade was disappointing. Considerable stocks were carried over at the end of the month, but there was no alteration in quotations. Prime quality clear extracted, 3d. to 3½d. per lb.; lower grades, 2d. to 2½d. per lb.

BEESWAX.—Came forward in fairly good quantities and ready clearances were effected, 1s. 4d. to 1s. 4½d. per lb. according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Thursday, and Friday and our sale rooms are the best equipped in the State. With the near approach of the visit of the Duke of Gloucester, the advent of the Royal Show in Adelaide this month, and expected influx of visitors to the city, the demand for poultry has been very brisk, especially as buyers were desirous of holding sufficient stocks in cold store to meet the increased trade. The catalogues submitted during the month were lengthy, but competition was keen for prime quality, heavyweight stock. We advise consigning. Crates loaned free on application. The following are prices realised:—Prime roosters, 3s. 6d. to 5s.; nice conditioned cockerels, 3s. to 3s. 5d.; fair conditioned cockerels, 2s. 2d. to 2s. 11d.; chickens, lower; heavyweight hens, 2s. 10d. to 3s. 6d.; medium hens, 2s. 1d. to 2s. 9d.; light hens, 1s. 8d. to 2s.; couple of pens of weedy sorts, lower; prime young muscovy drakes, 4s. to 5s. 3d.; young muscovy ducks, 2s. 3d. to 3s.; ordinary ducks, 1s. 1d. to 2s.; ducklings, lower; geese, 3s 3d. to 4s. 6d.; goslings, lower; turkeys, good to prime condition, 9d. to 10½d. per lb. live weight; turkeys, fair condition, 7d. to 8d. per lb. live weight; turkeys, poor and crooked breasted, lower; pigeons, 4d. to 6½d. each.

POTATOES.—Prime Victorian, 12s. per cwt.

ONIONS.—Brown Spanish, 12s. per cwt.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of September, 1934, also the average precipitation for September, and the average annual rainfall.

INDEX TO BUREAU REPORTS—*continued.*

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat v. Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep v. Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator v. Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

SOUTH-EASTERN DISTRICT.

KALANGADOO (Average annual rainfall, 32.30in.).

July, 1934.

SCRUB COUNTRY AND ITS MANAGEMENT.—Read by Mr. J. D. Hunt:—"In purchasing scrub land be careful not to pay too much for it, because if one should wish to sell it at any time there is not the same demand for this class of country as for the better class of land. The following scrub foliage is classified in order of preference for feed value. Swamp grasses and water rushes take first place, then follows Wire Rush, Sheoak Bush, Honeysuckle Bush, and Needle Bush in that order, and these are what one should look for when selecting a scrub block. Herbage which should be avoided: Fern and big Stringy Bark, Bull Honeysuckle, Black Boy, and Yaccas, which are of practically no food value. Look for low flat country with flood water on it in winter, the wetter scrub is the better. Endeavour to find out if all water holes, wells, and bores are permanent, a plentiful supply of water in the scrub is an absolute necessity, because the feed being of a dry nature the sheep need more water and for a longer period than those running on grass land. There are also the improvements to take into consideration—fencing, windmills, &c., the same as on any other property. The next step is to select the right kind of sheep. These should be between 4-tooth and full-mouthed Merino wethers or ewes, providing the ewes are not intended for breeding. Ewes run on scrub and taken off to be mated do not get in lamb readily. The sheep should be in sound healthy condition (not necessarily fat). They should be taken well into the paddock where it has been burnt and to the water. Inspect them every day or so until they have settled down; fresh sheep going into the scrub are likely to make back to where they are put into the paddock and hang there until thirst and starvation drives them out, which is very bad for the sheep and might cause a break in the wool. Burn about a third of each paddock each year. So far as possible, burns should lead out from the water. Should a patch on the east of the water be burnt and there is thick scrub between, wait for a west wind and burn a strip from the water to connect with the burn, and so on in other directions, as the case may be. Burning should always be done after the first rain, this does not scorch the ground so much, thereby injuring the roots of the herbage. The fence should be burnt every time the scrub is burnt, and the fence done up, for this is the only time that one can make a good job of doing up the fence, and if it is missed for a burn or two and then burnt, it is very hard on the wire as well as the posts. Avoid overstocking, if the scrub country is eaten out it takes longer to recover than grass land, because the strength is not in the ground. Change the sheep on to the grass land as often as possible, this balances the rations and helps to keep the sheep in good health." (Secretary, R. Messenger.)

June 21st.—Attendance, 12.

Breeding and Handling of Lambs for Market.—Paper read by Mr. F. Bryant:—"For crossbred lambs I favour the Merino ewe crossed with an English sire. For preference, use a 6-tooth to full-mouth, or even a cast for age ewe. A younger ewe is likely to give more bother when lambing and perhaps mean the loss of several ewes, whereas an old ewe is a good mother, and will not cause much bother in lambing. Young ewes—especially station-bred—are mostly culls, either because of wrinkles or poor quality wool; whereas older ewes are sold to make room for young breeding ewes which are coming on. Their wool will be of good quality and the ewes will be free from wrinkles. Wrinkles around the tail are a harbour for flies. When selecting a line of ewes for crossing, inspect the wool for quality, and select a line of large-framed ewes for preference. At present prices one may as well have sheep of good quality wool, for these ewes will not eat any more than an ordinary class of sheep.

For mating the ewes, I favour the first week of November, and then taking the rams away the first week of February; do not leave the rams in the flock all the year—this is too much on the ewe and she will never be in condition for growing good wool, When the ewes are lambing they require a lot of attention. Do this in the paddocks; avoid yarding them and keep the dogs at home. About three to four weeks after lambing is a very suitable time to tail the lambs. When tailed early, foxes do not seem to trouble them quite so much, the lambs recover quicker, and are not checked in growth. After yarding the sheep allow them to stand for about an hour or so before starting on the tailing; this will allow the lambs to cool down after driving and thus they will not bleed so much. Have a flat rail about 3ft. high and about 6in. wide on which to do the tailing.

Get the catcher to catch the lamb and then, sitting it on his knees, grip it with the hind legs in between the two front legs, holding the hind legs only. Hold the lamb firmly but not heavily, then place it on the rail ready for the tailer. As soon as the operation is finished, the catcher tilts the lamb slightly forward and releases his grip. This allows the lamb to fall forward and he stands on his hind legs. Never keep the lambs on the rail too long; they soon begin to struggle and kick and knock themselves about. In the case of a ram lamb, the marker stands in front of the lamb, then holds the tail with the left hand, and then with the forefinger and thumb of the same hand holds the back and front of the scrotum or purse. Then with the right hand, using the small blade of a penknife, start on the right hand side of the scrotum, with first a downward and then an upward motion, finishing on the left hand side of scrotum. The scrotum is opened by means of a slit allowing the testicles to come through; these are then drawn by the teeth for preference. As soon as this is done, dock the tail with a clean cut; do not pull the skin tight, but push it away, which means that there will be some left to cover the stump and thus assist in healing.

Many people in opening the scrotum cut the top right off. This is not a good practice; for one reason, it means that to heal, the skin has to grow over this opening, whereas in case of the slit, as soon as the lamb is on its feet again the scrotum falls into its natural position, thus the slit is closed and this soon joins together instead of having to grow a new skin over the scrotum. The healing process is much quicker and there is less likelihood of being trouble with flies.

Do the lambs as quickly as possible by having three or four catchers, thus getting them out of the yards instead of having them lying about where there is a possibility of them picking up germs. Open the gates and let them draw out of the yards slowly, holding the lead until every animal is out of the yard. Allow them to "mother up" before taking them away to the paddock, and when once in the paddock, hold them again until they have "mothered up" properly, then allow them to draw away quickly.

There are many ways of lambing; firstly, the knife as described, the pincers, and thirdly, the new way, which is by means of the burdizzo—a bloodless operation. I have tailed on an average about 7,000 lambs for the last 10 years, and have used all methods, but find the knife the best. Go out amongst the lambs as much as possible, seeing that they are free from flies and not wool blind. A common occurrence amongst sheep is pink-eye. This disease, if left to its own course, lasts about 14 days, and is very contagious. A little sugar put into the eye of a sheep is a good cure; it breaks the film over the eye, and once this is broken they soon recover. When handling lambs do not catch them by the wool—this causes a bruise, and it takes a long time for them to recover from this injury. If dogs are used when driving or handling see that they do not rush or ring the sheep, causing them to be knocked about.

Provided feed has been good, lambs should be ready for marketing when 14 to 16 weeks old. Exporters are nearly always operating at our markets, and they favour a lamb weighing between 70lbs. and 80lbs. live weight, equal to 32lbs. to 38lbs. when dressed. When the required weights have been obtained it is a good plan to kill and dress a lamb and see what it is like when killed. Then pick out a line to send away: do not send the best away first, but grade them. Put them into, say, three lines, and from these select and brand a line which may be termed as "feeler." These are mostly comprised from the second and third lines. These you will find catch the eye of a buyer and bring a good price. After killing he sees their condition, and knowing the brand will be on the lookout for another consignment. These, of course, will be better, and thus the bidding improves for your line. From then on select the tops, thus allowing the seconds to improve in condition.

When trucking, remember to keep dogs away, especially in the yards, and do not use sticks for poking them into the trucks. If hard to get started, take one up the ramp and hold it there until the others start, then gradually draw the leader into the truck, thus they will soon run right through the trucks on their own. Avoid shouting and rushing them around; they go much easier if taken quietly. Finally, when trucking, give details of the breeding of the lambs to your trucking agent, so that he may advise his firm at the Abattoirs." (Secretary, S. Herbert.)

YORKE PENINSULA DISTRICT.

BOORS PLAINS FIELD DAY.

"With anything like a reasonable finish there will be a lot of wheat come out of these districts this year." Thus did Mr. W. C. Johnston (District Agricultural Instructor) sum up the crops inspected on October 4th, the occasion being the Annual Field Day of the Boors Plains Branch of the Agricultural Bureau. Mr. F. C. Richards (Assistant Secretary Agricultural Bureau) and scholars of the Agricultural Class of the Kadina High School, in charge of Mr. McCarter, together with members of the Boors Plains Branch, first visited the property of Messrs. A. Rodda & Sons, "Churinga," Cunliffe. The holding consists of 2,400 acres, 900 acres of which are in wheat this year, the varieties being chiefly Sword, Waratah, and Gallipoli. Mr. Rodda said: "Sword has proved particularly suitable for this district. In 1931 I bought one bag from Roseworthy College. Since then I have sold 1,800 bags of it as Seed Wheat, and this year have sown it on 340 acres of fallow. It can be sown in any land at any time and will hold its own with any other variety." Other cropping

Boor's Plains Field Day.—Crop Inspection.

activities of this farm include 200 acres of Barley, 150 acres of Oats, and 700 acres of fallow. The Rodda Bros. are enthusiastic Clydesdale horse men, and at the present time have over 60 head of horses on their farm. Their head sire is Fairview Ambition, by Flashdale from Ochertyre Irene (N.Z.), and was bred by Mr. C. S. Rodda, a well-known Clydesdale breeder of Warracknabeal, Victoria. In common with practically every district of the State, paddock feed has been very scarce, and the flock of 300 sheep had to be hand-fed for over two months. Considering the dry weather experienced, crops are looking remarkably well. There is a noticeable freedom from disease, and Mr. Rodda expects a farm average yield of from seven to eight bags of wheat to the acre. To ensure adequate fodder supplies for next year, Rodda Bros. propose cutting 150 acres of crop for hay. A team of boys from the Kadina High School will take part in the Live Stock judging competitions at this year's Show, and Mr. Rodda brought in several of his mares and colts in order to give the boys the opportunity of brushing up their knowledge in readiness for the Show.

Mr. T. Stanway's holding of 1,800 acres was next visited. He has lived in the Boors Plains district all his life, and manages his property as a mixed farming proposition. His cropping programme for this year includes 500 acres of wheat—Sword, Waratah, Ranee, and Ford, the last-mentioned giving the appearance of yielding the best return—80 acres Oats, and 150 acres of Barley.

Perhaps the most noteworthy feature of the day's inspection was the marked attention that is being given to the management of Pigs. Only a few years ago most farms kept a few pigs to eat the waste from the kitchen and provide bacon and ham for the house. Nowadays many farmers are devoting no small amount of time to the care and management of this form of live stock. Speaking to Mr. Stanway about his pigs, he said: "I am running 70 head. I use the Large White boar, mate him to a Berkshire sow, and then bring the sows in that litter back to the Large White boar. This year," he said, "I have had a wonderful run with pigs. Apart from the meat meal, I grow all the feed they consume on the farm. The grain I soak and feed in the proportion of 1 of wheat to 5 of barley. Barley for which last year I was offered 1s. 10d. to 2s. per bushel has returned to me 3s. 3d. to 3s. 6d. when fed through pigs."

Boor's Plains Field Day.—On Messrs. Rodda & Sons' Farm. Mr. Rodda explaining points of a Clydesdale mare to Boys of the Kadina High School.

Mr. Stanway attributes most of his success with Pigs to the care he gives the youngsters during the first 10 weeks after they are born. He said: "The last 60 pigs that I have delivered to the Abattoirs have netted me 63s. per head." Mr. Stanway has a nice Jersey herd and is milking 11 cows. The sire is Brinkworth Chris, by Geneva Chris of Penrith. The skim milk from the cows makes a valuable addition to the food supplies for the pigs.

The party then went on to the farm of A. Yelland & Sons. The first crop inspected was 150 acres of Ranee. It was clean and level, and Mr. Johnston, on being asked to make an estimate of its yield, said: "27 bushels if the season does not 'shut up' too quickly."

Altogether there are 700 acres under Ranee, Sword, Waratah, Daphne, and Nabawa wheats. Livestock activities are represented principally by Fat-lamb raising and Poultry, the latter being conducted on a fairly large scale. Mr. Yelland has 300 laying hens—Minorcas and White Leghorns—and has this year raised 600 chicks. So well have his Minorcas laid this year that next year he hopes to enter a pen in the Parafield Egg-laying Competition.

The last property inspected was that of Mr. S. Chynoweth, the capable Secretary of the Boors Plains Branch. A noteworthy feature of the paddocks under crop was the exceptionally wide breaks that had been left as protection against fire. "I am surrounded on all sides by tractor farmers," said Mr. Chynoweth, "and it is better to be sure than sorry." Mr. Chynoweth's holding is a comparatively small one—710 acres of arable land; 50 acres of scrub have been left to provide shade for livestock and firewood supplies—the latter is becoming quite a problem in the district—360 acres are sown with wheat and 150 acres of malting barley. Mr. Chynoweth expressed the opinion that crops generally speaking were up to standard, the best of them being on the stoney rises. He is another farmer who is devoting a good deal of time to Pigs, and is convinced that the right type of Large White boar is the best sire for pigs for both the local and export markets. He normally runs about 100 pigs, and in the last four years his porkers have not been beaten in the Kadina Show. The herd has been built up from boars from Mr. A. J. Aldridge's Gawler River Stud. Mr. Chynoweth keeps a careful record of his activities with pigs. The skim milk and barley are produced on the farm, and barley for which he was offered 1s. 9d. per bushel last year was worth 3s. 10d. per bushel fed through his pigs. The poultry are managed by Mrs. and Miss Chynoweth and 50 dozen eggs are marketed each week.

Other farms visited were those of Messrs. M. D. Wright and L. Northy.

WESTERN DISTRICT.

MANGALO (Average annual rainfall, 14in. to 15in.).

CLEARING NEW GROUND.—Paper written by Mr. A. Hannemann.—"This paper refers to the western portion of this district. The scrub should be rolled down in spring and left to dry during summer. Clear a break around the scrub by throwing the scrub in around the edge about 6ft. wide, and then clear a strip about 50 to 60 yards from the edge. This piece between must be burnt out on a cool night. After the scrub is burnt the remaining sticks must be heaped up and burnt if it is to be sown with a combine. A better plan is to leave the sticks where they are and work the land with a disc plough, and then drill it. The plough will pull off a lot of the spring-backs, and they will be very acceptable for the first stubble fire. After seeding is completed, all remaining sticks should be cut. An early wheat should be sown on new ground ,so that it can be reaped before the shoots are too high. A roller of some description should be tied behind the stripper to knock down the straw for fire raking. If summer rains fall, and the ground cannot be burnt, it should be fallowed. If the ground is burnt sow it with either wheat or oats with the plough and drill. The plough will tear off the dry shoots. In the gullies is the only place where the shoots need cutting, and if the straw is rolled again another burn should be obtained. Then fallow with a disc plough and sow a wheat crop the next year, the stubble of which can be burnt. The following year the best plan is to sow with oats and burn off again. Then it can be left for for a feed paddock or fallowed. When it is fallowed stump picking is an endless job."

SOME SUGGESTIONS ON HOW TO BECOME A SUCCESSFUL FARMER.—Mr. J. Evely read the following paper:—"For the purpose of this paper I have divided farmers into three classes—The successful farmer (*i.e.*, free of debt); the farmer harassed by debts and financial difficulties; and the farmer in embryo. (1) The successful farmer has his own experience to guide him, and need not come into this discussion. (2) The harassed farmer needs far wiser heads than mine; but (3) the farmer in embryo, is young and full of hope. He is neither successful nor harassed, but needs careful guidance and training to put him into class 1 and keep him out of class 2. Here are some points worth considering by both himself and his parents—(1) He should never enter into debt. By starting young (12 years) he could establish his stock (sheep, cows, horses) with his parents' assistance—and is this not a duty of the parent? He should be thrifty and swell his banking account with the profits from his stock, wages, and any other project he may run. He should watch his opportunity to buy a cheap farm—and quite often these are available—but pay cash for it. If unable to do this, he should either rent a farm or wisely enter share farming, but always have the principal necessary in hand before commencing any of these three. (2) He should leave mortgages alone. Taking out a mortgage is not a debt (it is an exchange of value for value), but the mortgagee makes himself liable to lose all his previous outlay unless he can repurchase his mortgage with interest added. In 12 years at 6 per cent. the value of a mortgage doubles itself. To take such a risk as a young farmer very often means a burden that will gradually—or quickly—lead him into the unenviable position of the class 2 farmer. (3) He should keep a careful check on all expenses in all things all the time. A careful ledger should be kept showing receipts and expenditure with a yearly balance-sheet. and this should be constantly referred to for future guidance. Without such figures he cannot wisely estimate his future expenditure, nor be sure of which sections of his farm are paying and which are failing. It will also show him quickly and clearly any exorbitant expenses or dangerous balances. (4) He must establish a reserve fund as soon as possible, and increase it rather than decrease it to meet emergencies. This is a fundamental of all sound business undertakings. (5) He should never ridicule, nor pass off lightly the advice of an experienced farmer (whether his parent, neighbour, or Government official). They have had years of practical experience that he has not. Nevertheless, if he is to be a successful farmer he must learn by study, experiment, and experience to make his own decisions. (6) He should educate himself sufficiently well to be able to wisely run a farm. Blacksmithing, harness work, mechanics, shearing, veterinary studies, and particularly arithmetic, are all important studies very often neglected by farmers to their own disadvantage and financial loss." (Secretary, R. Turner.)

NUNJIKOMPITA.

June 28th.—Attendance, 15.

LIME BURNING.—Paper read by the Secretary, Mr. P. Luestner.—"A lime kiln may be made anywhere where the sinking is good, but not on sandhills, because the heat and working at the pit will cause the sand to cave in. A kiln should be built accord-

ing to the quantity of lime wanted, and, when full, be as high above the ground as the depth. A small disused underground tank is ideal for burning lime, it remains clean from dirt, and when shovelling out there is a hard floor to shovel from. In building a lime kiln after it has been dug out, a layer of about 1ft. of mallee boughs should be spread over the bottom, then about 2ft. of mallee stumps, 1ft. of limestone no larger than 3in., and this method continued—a layer of stumps and stones until the top is reached, when it should be finished off with the largest and most solid stumps. It is necessary to have vents in each corner and the centre. Hollow trees are ideal for this. When lighting a kiln, a gallon of petrol can be used to ensure a good start. In selecting stone for burning lime, the harder the stone the better the lime will be, and the longer it will keep in good condition. The red granite-coloured stone found in this district makes better lime than the pure white stone. White stone, when burned, will slake in about three weeks, but the red stone will keep for two or three months.''

WARRAMBOO.

June 8th.—Attendance, 11.

A paper entitled ''The Management of Livestock'' was read by Mr. H. Chilman:—''In these day of low wheat prices it is advisable for farmers to pay more attention to the management and breeding of livestock. The most profitable animals to have on the farm are sheep, for they do not, for the greater part of the year, need very much attention. I do not consider this district suitable for the breeding of fat lambs, so breeders should concentrate on securing a good wool clip. Another very profitable side-line at present is breeding pigs. The best results will be obtained by using a Large White boar on selected sows of the long, lean type. The pigs should not be carrying much fat on the backs, hams, or bacons; smaller hams are preferred, and the pigs should have a large yard to run in as they develop much better. Every farm should have a few cows. I do not think it is advisable to have very many—it is better to keep just two or three and give them more attention. Before calving, a cow should be rested from six to eight weeks and should be in good condition when she calves. A new born calf should be left with its mother for 24 hours and receive its mother's milk for several days. If a calf is well looked after and fed during the first few weeks of its life it will turn out to be a better cow later on. Mix a little bran with the milk on which the calf is fed, and as it grows older the best feed is crushed oats. After the cow has calved, the afterbirth should come away cleanly. If the cow does not get rid of it properly it will cause inflammation and the cow will be very hard to get in calf again. A good disinfectant is as much Condy's crystals as will go on 6d. in 1 gallon of water. Trouble in the udder should be treated at once to prevent mammitis. Apply hot fomentations and rub in camphorated oil or 8 parts of olive oil to 1 of eucalyptus. If a cow has milk fever, she will be lying down, generally on her right side with the head turned round to the flank and in an unconscious condition. Pump up the cow every two hours until she is on her feet; it will not be necessary to tie the teats. If they are tied the teats will be bruised. If a cow is fed with lime six weeks before calving, she will probably not be troubled with milk fever. For cows with colic, give the following drench:—1 tablespoon Epsom salts, 1½lbs. treacle, and 4 tablespoons ginger. For a cow with gas in the paunch, give Stockholm tar and make a bit with thick rope dipped in tar. If it is necessary to open a cow, put in the knife on the left side, midway between the hip and last rib. A very good lick can be made from the following ingredients:—Coarse salt 20 parts, air-slaked lime 30 parts, bonemeal 50 parts. This lick is most needed when feed is dry.'' (Secretary, F. Chilman.)

July 6th.

SANDHILLS.—Mr. P. Daniel read the following paper:—''Personal experience has proved to me that the more sandhills drift in the paddock the better crop they and the adjoining flats grow. Along roads the best thing to do is to keep fences clear of rubbish and sow oats for a couple of chains in. These can be fed off with sheep, and the roots of the plants would help to bind the sand and keep it from drifting. In dry years the flats do more damage with drift than old sandhills. The main thing is to clear the sandhills of roots and stumps as quickly as possible. Dry ploughing will pull out more stumps than wet ploughing. Two years ago I had new ground burnt the year before, but was unable to crop or fallow it. This had a big sandhill. I used a foot plough in this paddock when it was wet in the early part of June, with the mouldboard down the hill. The result was stumps that took a lot of picking, but a good crop right to the top, and then a good burn. It is far better to plough sandhills as new ground than fallow them. The crop helps to keep the sand from drifting into heaps and hollows over the rubbish, and it is impossible to pick everything clean enough to stop this. After the second ploughing with a good foot plough,

there are not many stumps left or much rubbish, and the hills blow evenly. I do not advocate a disc. This implement, no doubt, does the same job so far as producing a good crop is concerned, but it does not put the farm ahead in clearing out the stumps and roots while they are green. Shoots are a lot easier killed after a good ploughing. Thirteen years ago I had a plough and used it for one seeding. The sandhills that were ploughed then are clean and grow good crops. For four years I used the cultivator; this was quicker, but did not clean out the stumps. If these paddocks were left out for a few years, the sandhills—although they were fire raked every year—would have just as many shoots as before, besides drifting into hollows and ridges. I then used the combine, which, of course, acted the same as the cultivator. For the last five years I have been using the heavy plough. This means a lot of stump picking, but all the sandhills that have been ploughed twice are practically free from stumps and rubbish, excepting for a bit of undergrowth bush, which will, no doubt, trouble us for a few years yet. It is far better to pick one stump than to cut the shoot on it half a dozen times. Unfortunately we cannot always do as we would like in this country, because of the large areas and lack of finance. I advise the first two years wheat, then, if possible, fallow before the first rains. This would provide feed from a self-sown crop, which would be better than winter fallow and turning under the self-sown crop, providing, of course, it could be kept clean with sheep. Being practically new ground, there should not be anything further than self-sown to worry about. If unable to fallow, sow oats, burn the stubble, and then fallow. A good ploughing and two or three burns, then fallow, and the sandhills will be clean. My experience has been super the sandhills as heavy as one can, they will grow better crops. One sandhill I cropped in 1920, ploughed the next year, and then sowed wheat until 1927. On the sixth crop I put one bag of super to the acre. It made a fair improvement that year, but the next year the crop was very high and thick. The last crop went out in barley grass. We had no trouble with takeall or in keeping the ground clean for a number of years, until the older paddocks started to grow barley grass. One naturally looks for takeall to show first in the sandhills, so that I advise working the following four-year rotation after new ground:—(1) Fallow; (2) wheat; (3) oats for hay, seed, and standby for stock; (4) oats without super to be fed off. This enables a farmer to procure the best out of the land, without any fear of takeall, and to stock very heavily with sheep. Fences should never run along the top of sandhills, because the sand blows out and the posts fall down. Where fencing runs over the sand, all shoots and rubbish should be kept clear. Plough around the fences as close as possible—using leaders. Most farmers rely on the fire rake, my experience has been the plough first, with the fire rake second place on our farms. This will give a running burn.'' Mr. H. Tucker read a paper on "Fencing.'' (Secretary, F. Chilman.)

EASTERN DISTRICT.

LONE GUM AND MONASH.—June 21st.

Asked as to the correct methods of pruning Malagas, Grenache and Shiraz, Mr. N. Fotheringham, Manager of the Berri Orchard, said:—Malagas were rod and spur or just spur pruned (either method, but rod and spur was preferable); Grenache, spur pruned; Shiraz, rod and spur. "Is gypsum detrimental or otherwise on salty ground?" was answered to the effect that in the case of black alkali, it was effective, but as most of the salt in this district is of the other type, it had little effect on the soil. Would it be advisable to cincture grafted currants with a strong growth, having four arms formed? Providing the growth was good, the speaker advised the use of a single cut, but no more. The best time to plough oranges, was asked, to which a reply was given that as citrus roots became active early, having a very short dormant period, now would be an opportune time.

Cinturing of Vines.—Mr. Fotheringham was asked had he had any experience with second cincturing of currants. There were no tests in this connection, but he said he had done it to counteract the effect of water at an inopportune time. To effect the setting of the end vines the speaker thought this method might be effective —a double cut at first and followed about 10 days later with a single cut. The observations at the Government orchard at Berri had led them to advocate cincturing when the caps were falling freely on the ground. Cincturing when the fruit was the size of a shot had been tried, but did not give the required crop. Mr. Fotheringham was asked his opinion as to the value of sulphur when drilled in. Generally speaking it was shown to be of little manurial value, however the Waite Research Institute were experimenting in this direction, and he understood that in their work they had isolated another bacteria and this might lead to results with a good effect. This work was being carried out and tests taken—it was too early to speak of definite results yet. The various methods of training the currant vine came up for discussion. Various systems tried out at the orchard were explained by Mr. Fotheringham. The best results had been shown by vines trained on the three-armed espalier method which, over a period of 16 years, had shown an average yield of 5,105lbs. Questioned as to whether the growth would not ultimately go to the top wire, he stated that it was shown that approximately 50 per cent. of the growth went to the top wire; this, however, was growth, not fruit. The vines under discussion had always been pruned that way and had maintained their crop.

SOUTH AND HILLS DISTRICT.

SHEEP DIPPING ON THE FARM.

[*Paper read by H. Higgins at the June meeting of the Currency Creek Branch.*]

For upwards of 100 years the battle has gone on between the manufacturers of sheep dip and the chief parasites of sheep—the louse and the ked, commonly known as the sheep tick.

There are roughly three classes of sheep dip made, namely:—(*a*) The Arsenical Powder Dip; (*b*) the Arsenical Liquid Dip; (*c*) the Non-poisonous Liquid Dip; and of these three, the first two are most generally used, employing as their destroying agent the poison arsenic.

It has been found that this poison in combination with other substances makes the safest and most useful compound to use in the destruction of parasites. It is applied extensively with lead as a spray against the codlin moth, with sodium against cattle tick, and with sulphur as a destroyer of sheep louse and tick.

In every case water is used as a carrier of these poisonous compounds, the idea being to cast a film over the animal or fruit, of very small particles of arsenic; so that the parasite, when feeding on its host will devour some of this poison and die. This actually does take place, but there are other dips made called non-poisonous, these depend on coming in contact directly with the parasite, to destroy it, and are known

as contact dips, as against the arsenic varieties which depend for their success on the poison getting into the stomach of the parasite, and are therefore known as stomach poison dips.

Manufacturers have never had much difficulty in making a dip to destroy live lice or tick, in fact if this were the only trouble, the writer ventures to say that the starlings and willy wagtails with the help of the sheep would make quite a good job for the first two months.

The female louse, it has been computed, lays about 5,000 eggs at a time, and these usually hatch out in 6 or 7 days, and in 11 or 12 days from this the females are ready to reproduce their kind. The eggs of the tick on the other hand take 21 days to hatch out, and under unsuitable conditions such as a cold period, have been known to run as long as 42 days. The young ticks take about the same time to mature as the louse; but it is the sheep louse that is most to be dreaded, as it can spread through a flock with very great rapidity.

The late Inspector Williams, who made a very careful study of these enemies of the sheep farmer, pointed out that the control of the tick was an easy matter when compared with the louse, and he went on to say that he knew of a case when a single ram infected with lice made the whole flock dirty.

Manufacturers of sheep dip must provide that the poison they employ to destroy the parasites should remain on the skin of the host in such quantity as to destroy the young parasites when hatching out. If the period required was only, say, 42 days, the task might be a fairly easy one; but as dipping in the various parts of the State begins from about the end of October and goes on even as late as February, one can readily see that sheep dipped in October would have to run the risk of infection until the February farmer has dipped his flock—probably 3 months later. Then, of course, there are the strays missed at mustering which never get dipped at all, and so, to have a really efficient dip, the farmer must use one which retains its poison on the skin for the longest period.

The difficulties of the manufacturer can be grasped to a certain extent, even by the novice, when one realises that the poison must remain active on the sheep in spite of evaporation or heavy rain; in fact some well known manufacturers are quite frank over the matter and readily admit that their sheep dip has a very definite life of usefulness, and that there comes a time when dipped sheep, if allowed to run with those undipped, will become infected.

For this reason I favour a stomach poison dip in lieu of a contact one.

My experience of some 30 years bears this out, for during that time I have used several makes of sheep dip, all of which have been most effective on the live parasite, and then tailing off in their usefulness as time went on. I have often crutched my whole flock in May without finding a single tick, but I cannot say this when shearing arrives.

Not only has the manufacturer to contend with the period of incubation of the egg, the weather, either of heat or rain, to spoil his dip, but he must use a poison that will not injure the wool on the skin or as it emerges therefrom, and when one has examined in detail the intricate way in which wool is produced, one can easily understand how careful the maker must be to use a safe poison.

The wool commences its journey through the skin from a network of nerve centres and blood vessels, and it is quite possible that some sheep less robust than others could have a check in the growth of its wool by some sudden shock such as dipping; but in 9 cases out of 10 the break is really due to lack of nourishment, impairing the blood supply, which helps to produce the wool and also the grease commonly known as yolk. The yolk serves to oil the fibre on its passage to and whilst exposed to the air.

Sheepmen could improve the results of dipping in many ways, and I have often seen a sheep dip condemned, though the user has to a large extent completely ignored the maker's directions.

We are apt to make the dipping fit in with out farm work and take second or third place to other business, for instance, the amount of wool to carry the poisonous particles of dip is very important; if too short, evaporation or rain can destroy a large amount of its usefulness; if too long, considerable difficulty will be experienced in getting the poison on to the skin where the parasites feed. Especially is this the case in many of the short-swim dips about the State; and also the sheep are often hurried through, many not having their heads and backs thoroughly soaked.

Dipping is necessary because the parasites, if left unchecked, would injure the wool and stunt the growth of the sheep, the loss through the presence of these parasites many times out-weighing the cost of dipping. Every sheepman must admit that the dipping does act as a check in the condition of the sheep for approximately 2 weeks, and it is unfortunate that this has become so necessary.

There is also a certain amount of loss through dipping for which often the dip is blamed; even under the most careful conditions a few sheep invariably die, although the percentage is hardly noticeable. Most of the deaths I venture to say would occur

if plain water were used [illegible] that the [illegible]ep is called upon to swim up to 60[illegible] is not natural to the animal, and finds out any [illegible]st.

It must be understood that not every sheep is perfectly physically fit, and this **thorough soaking** coupled with perhaps **a change** in the weather, may bring on **pneumonia.** Also, dipping fat sheep overheated by travel is an almost certain way to cause mortality, and the writer has experienced loss in this way, especially with fat rams. An odd sheep or two may be lost through blood poisoning, for germs can get into the blood stream through cuts, bruises, or dog bites, and it is far more difficult to disinfect a sheepyard than a woolshed.

In conclusion I would like to suggest a few very important points relating to dipping but which are well known to most of you, and may seem superfluous.

SUMMARY.

(*a*) Begin dipping with a clean bath of known capacity, and check the quantity of water put in to each packet of dip.

(*b*) Have a strainer or sieve to skim off the foreign matter which always becomes present with dipping.

(*c*) Dip sheep under pleasant weather conditions, and see that the sheep have had a good rest before dipping, preferably the night before.

(*d*) Keep the bath well stirred and see that each sheep is thoroughly immersed.''

SPRINGTON AGRICULTURAL BUREAU.

The Annual Pruning Competitions conducted under the auspices of the Springton Branch of the Agricultural Bureau were held on July 18th. Messrs. W. Bietz, of Tanunda, and E. Leishman (Horticultural Instructor of the Department of Agriculture) acted as judges and made the following awards:—

Competitor.	Shiraz.	Grenoche.	Total.
G. Starick	89	92	181
H. Eckert	89	90	179
H. Lorke	92	85	177
E. P. Filsell	84	93	177
J. Kruger	89	88	177
R. Rayner	91	84	175
C. Lorke	86	88	174
R. Starick	83	90	173
K. Engel	88	84	172
E. Brokate	85	85	171
W. Kluge	91	80	181
I. Wegener	86	85	171
W. Lorke	90	81	171
R. Moody	82	85	167
K. Bishop	86	80	166
M. Kroehn	86	—	86
D. J. Bain	—	84	84

WOMEN'S BRANCHES.

SUBJECTS FOR BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme.

The Farm.	The Home.	General.
Dairying—	Home Management—	Inter-Branch Visits
Care of Milk and Cream	Furniture—	Competitive Exhibition
Buttermaking	Choice	Flower Show
Cheesemaking	Repairing	Practical Demonstrations
Pigs—	Needlework	Social
Bacon Curing	Knitting	Music in the Home
Beekeeping—	Rugmaking	Good Reading
Honey	Clothing—	Hobbies
Horticulture—	Choice	Physical Culture
Vegetable Growing	Repairing	Labor Saving Hints
Flower Growing	Dressmaking	Spring Cleaning
Poultry—	Pattern Afternoon	Entertainment in the Home.
Dressing	Children—	
Incubation	Care and Management	
Rearing Chicks	Cooking—	
Turkeys	Recipes	
Ducks	Recipes for Christmas	
	Lunches	
	Jam Making	
	Fruit Preserving	
	Fruit Drying	
	Fruit, Value of	
	Pickles and Sauces	
	Sweet Making	
	Exhibition of Home Crafts	
	Christmas Gifts	
	Home Nursing	

GOOD THINGS FROM THE OVEN.

[By GRACE B. ARMSTRONG, A. MARIE SCHRIEBER, and MARY A. MCPHEE, of the University of Illinois, Urbana, U.S.A.]

COOKIES.

Cookies are small cakes made thin and baked quickly. They contain practically the same ingredients as do ordinary cakes but in different proportions since the small, flat cake may be made very rich. In addition to wheat flour, oatmeal and various other flours may be used in cookies. The technique of making perfectly shaped, well-flavoured cookies is somewhat hard to master. When first learning, it may be necessary to use more flour than is needed later.

Use the general method for mixing cake previously described.

The amounts given for each recipe are only approximate. The number of cookies will depend on size of cutter and thickness of dough.

Method of Rolling.

How.	*Why.*
Put small amount of flour on kneading board. On this flour put about 3 heaping tablespoons of cookie dough. Do not take out a large quantity of dough at a time.	A very small amount of flour is sufficient to keep dough from sticking to board. If cookie dough is handled too much and flour is mixed into it, cookies are often stiff and tough.
Turn dough over so that floured side is on top. If necessary, again sift a small amount of flour on board.	
Roll lightly, lifting rolling pin frequently and rolling in a different direction each time until the dough is about ¼in. thick.	If pressure is exerted dough is likely to stick to board.
With a cookie cutter, cut cookies as near each other as possible. Try to avoid leaving any large irregular pieces of dough.	The amount of trimming should be as small as possible for this dough must be rolled a second time. Dough that is worked over is not so light as the first dough and is often too stiff for best results.
With a spatula or flexible knife, lift cookie off board, and without handling it place it on a greased cookie pan.	Cookie dough is very sticky, and if touched will stick to the fingers and make a badly shaped product. With a little practice, one can easily slide cookies off the spatula without touching them.
A little sugar may be sprinkled on top of cookies before putting them into oven.	The sugar gives cookies a finished appearance when baked.
Gather up trimmings and roll again until all dough is used.	

Method of Baking.

How.	*Why.*
Bake in moderate oven (375°F.) for 5 to 7 minutes.	Cookies should be baked quickly so that they will not dry out, but they should have a medium-brown colour.
When baked, remove from pan by slipping a spatula or flexible knife under cookies. Place them on a wire rack to cool before piling in a jar.	Cooling before storing helps to keep cookies well shaped and crisp and prevents them from sticking together.

Oatmeal Drop Cookies.

Equipment.

- 1 mixing bowl
- 1 measuring cup
- 1 teaspoon
- 1 mixing spoon
- 1 flour sifter
- 1 spatula
- 1 food chopper or chopping bowl
- 1 mixing knife
- Baking pans

Materials.

1 c. sugar	$\frac{1}{2}$ t. soda
$\frac{2}{3}$ c. shortening	1 t. baking-powder
$\frac{1}{2}$ c. sour milk	1 t. cinnamon
2 eggs	$\frac{1}{4}$ t. cloves
1 t. lemon extract	$\frac{1}{4}$ t. nutmeg
2 c. oatmeal	1 c. raisins and currants
2 c. flour	1 c. nuts

Amount: 4 or 5 dozen cookies.

Method.

Use general method for mixing cake. Combine in order given above. The oatmeal should be added to the liquid ingredients and allowed to become thoroughly moist before flour is added. Chop fruit and nuts, flour well, and add at the last. Stir until well blended. Drop from a spoon on to greased pans. (These cookies will have a better shape if a small spoon is used to push the dough off the stirring spoon.) Bake in moderate oven (375°F.) for 8 or 10 minutes. Keep in a covered stone jar. The flavour is better after cookies have been kept a few days.

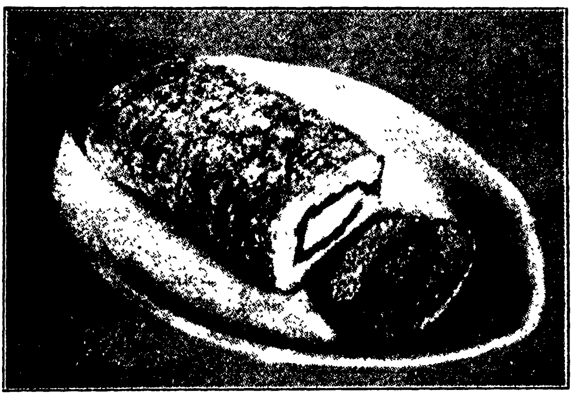

Fig. 13.—Jelly Roll.

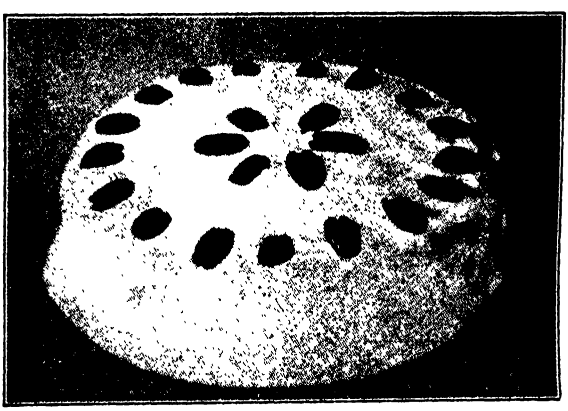

Fig. 14.—Layer Cake, filled and iced.

Fig. 15.—Devil's Food Cake.

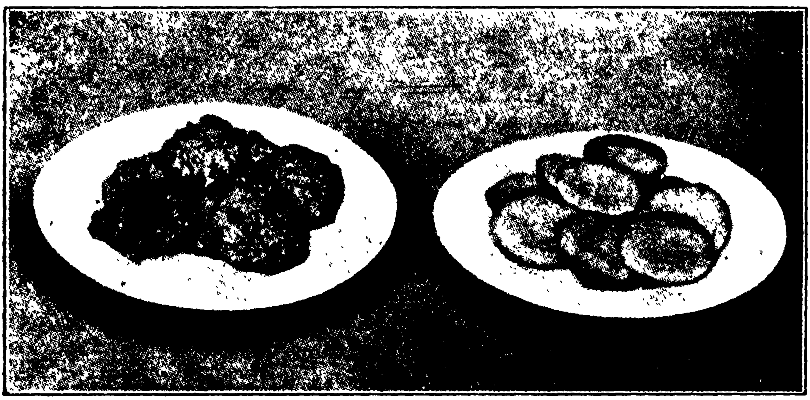

Fig. 16.—Oatmeal Drop Cookies and White Rolled Cookies.

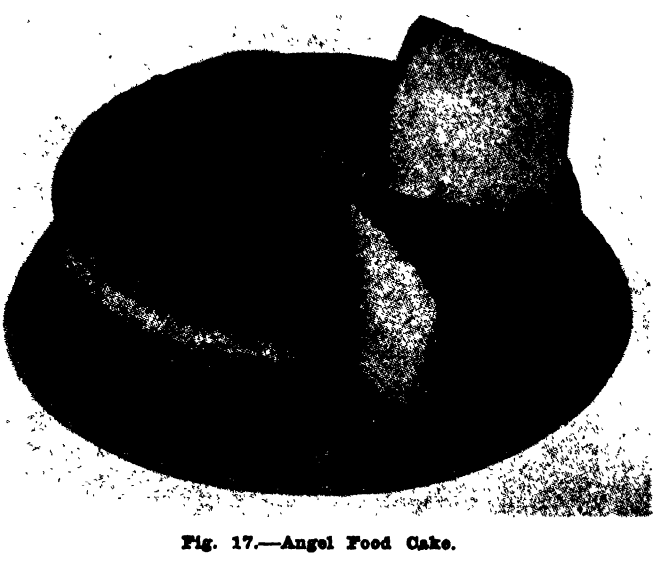

Fig. 17.—Angel Food Cake.

WHITE ROLLED COOKIES.

Equipment.

1 mixing bowl	1 board
1 measuring cup	1 rolling pin
1 teaspoon	1 spatula
1 mixing spoon	1 flour sifter
1 cookie cutter	Baking pans

Materials.

½ c. butter	½ t. lemon extract
1 cup sugar	2¾ c. flour
½ c. milk	2 t. baking powder
2 eggs	½ t. grated nutmeg

(Variations may be made by adding chocolate, fruit, or nuts.)

Amount: 4 dozen cookies.

Method.

Use general method for mixing cake and general method for rolling cookies.

MOLASSES COOKIES.

Equipment.

Same as for white rolled cookies except for addition of small saucepan.

Materials.

½ c. shortening	2½ c. flour
½ c. molasses	½ t. soda
½ c. sugar	½ t. cinnamon
¼ c. cold water	½ t. ginger
½ t. vanilla	⅛ t. nutmeg
1 egg	

Amount: 5 dozen cookies.

Method.

How.	*Why.*
Place shortening, sugar, and molasses in saucepan. Mix well and bring to boiling point. The mixture must be carefully watched and stirred because it burns easily.	Cooking thoroughly blends these ingredients.
Remove from fire. Add cold water, stir well, and allow to cool before other ingredients are added.	A warm product requires more flour to prevent stickiness than does a cool product. If mixture is not allowed to cool, there is danger of making cookies too stiff. Mixture must be cool to prevent coagulation of eggs.
Add beaten eggs and vanilla. Sift and add dry ingredients. Stir well.	

In rolling follow general directions (see page 420), but remember that molasses cookies should not be rolled as this as either white cookies or ginger snaps. Bake in moderate oven (350°F.) about 10 minutes; watch closely. Great care is required in baking these cookies because the molasses in them will cause them to burn easily. These cookies will keep moist a long time. A variation of them may made by adding nuts, in which case less shortening is used.

Ginger Snaps.

Equipment.

Same as for molasses cooking.

Materials.

1 c. molasses	½ t. soda
½ c. fat	1 Tb. ginger
3¼ c. flour	1½ t. salt

Amount: 7 dozen cookies.

Method.

How.	*Why.*
Heat molasses to boiling point and pour over shortening.	Boiling molasses even slightly condenses it. Hot molasses melts shortening, and the mixture serves as a liquid into which the other ingredients can be blended.
Add dry ingredients mixed and sifted. Chill thoroughly.	Dough is more easily handled and can be rolled thinner when cold.
Roll as thin as possible. Cut into small cookies. Keep bowl in a cold place during the rolling process.	If dough gets warm, it will be sticky; more flour will then be needed and cookies will be stiff rather than crisp.
Bake in moderate oven (350°F.) about 10 minutes. Allow to cool before packing.	Ginger snaps lose their crispness if packed while warm.

Ice-Box Butterscotch Cookies.

Equipment.

1 mixing bowl	1 *sharp*, thin-bladed knife
1 mixing spoon	1 flour sifter
1 measuring cup	Baking pans
1 teaspoon	

Materials.

1½ c. butter	2 eggs
2 c. brown sugar	3 c. flour
2½ t. baking powder	

Amount: 5 or 6 dozen cookies.

Method.

Cream butter, add sugar, then beaten eggs, and mix well. Add flour and baking powder sifted together. Mix and knead slightly. Shape into a roll, then chill thoroughly. Slice ¼in. thick. Bake on ungreased pan in moderate oven (375°F.) for about 10 minutes. The dough may be kept in a refrigerator for several days, then sliced, and baked as fresh cookies are desired.

UNSHORTENED CAKES.

Ingredients.

Sponge cake is typical of cakes made without shortening. Since the gluten is not shortened and egg white are the only leavening agent, special care is needed in combining the ingredients.

The sugar should be fine. Only fresh eggs can be beaten sufficiently to make a light product. Any soft-wheat flour or pastry flour may be used; since the gluten is unshortened, bread flour would make a tough cake.

Method of Mixing.

The mixing of a sponge cake requires much more skill and care than the mixing of a shortened cake.

General Method.

How.	*Why.*
Sift sugar.	Sifting removes lumps and separates grains of sugar so they are easily dissolved in the small amount of liquid used.
Sift flour 4 or 5 times before measuring and be careful not to pack it in cup when measuring.	Sifting increases bulk of flour by separating the particles and incorporating air between them. Also, if the particles of flour are separated they can be mixed more thoroughly and easily with egg whites. Ever so little extra flour may make a sponge cake too stiff.
Separate whites and yolks of eggs.	Since air is the only leaven used, it is necessary to beat egg whites separately so that a larger amount of air may be incorporated.
Just before they are to be used, beat egg whites with a wire beater until *stiff*, or until they will stay in the bowl when it is inverted. Do *not* beat them until dry. (Lift beater up and out of the egg whites with each stroke.)	Beaten egg whites quickly lose their lightness on standing. A wire egg beater makes the product lighter than does a Dover beater. If beaten until dry, the albumin walls will have been stretched so far that they will be very fragile and will not stand the strain of further beating or the addition of other ingredients.
Mix other ingredients with beaten egg whites by using cutting and folding motion. To do this put the spoon or spatula edgewise into middle of the dough, slide it under dough and bring it up at the edge of bowl, at the same time folding that part of dough toward the centre. Turn bowl each time so that a new portion of dough is folded over. Try not to stir product but let the cutting and folding motion thoroughly mix egg whites into dough.	Any other method of mixing would break the delicate albumin walls; the leaven would escape and product would be heavy. As an illustration, beaten egg whites may be compared to the honeycomb and the incorporated air to honey in the comb. When cutting a comb of honey, very little of the liquid is lost if a knife is used and a straight cut is made down through comb; but if it is stirred with a spoon, many cells are broken and much honey lost. In the same way the cutting and folding motion used in incorporating beaten eggs into a mixture breaks only a few of the albumin cells.
Carefully slide cake mixture out of mixing bowl or platter into an *ungreased* cake pan.	Sliding the mixture tends to preserve air cells of beaten egg white. By leaving pan ungreased a surface is furnished to which cake will cling as it rises, thus helping it both to rise and to keep its shape.
Use a standard angel food cake pan.	The hollow stem in centre makes it possible for heat to penetrate evenly to all parts of cake.

Baking Unshortened Cakes.

As already stated, the baking of a cake largely determines its success. The oven should be hot enough at first to expand the air rapidly and start the cake rising, but it should not be so hot as to form a crust or start the browning. Since egg white coagulates at a low temperature, produces made of it must be cooked very carefully. However, if baked too slowly, the cake is likely to dry out and not rise sufficiently.

This type of cake should bake in a slow oven (300°F.) 1 to 1½ hours, the exact length of time depending on its size. Do not open oven door for first 20 minutes of baking. Be careful not to jar oven while cake is baking. When done, invert cake pan over a wire rack in a place free from draughts and allow cake to hang in pan and cool gradually. If removed from the pan while warm, cake will fall because the delicate albumin walls have not completely set.

For serving cut with a thin-bladed, sharp knife, using a light, quick stroke, or pull apart with two forks.

Sponge Cake.

Equipment.

1 platter or big bowl	1 mixing bowl
1 teaspoon	1 grater
1 egg whip	1 measuring cup
1 flour sifter	1 rolling pin
1 tablespoon	1 cake pan

Materials.

5 egg yolks	1 Tb. cold water
1 c. sugar	¼ t. salt
½ t. grated lemon rind	5 egg whites
1 t. lemon juice	1 c. flour

Amount: 1 cake 9in. in diameter.

Method.

How.	*Why.*
Roll and sift sugar. Sift flour before measuring. Be careful not to pack it in cup when measuring.	Rolling sugar makes it finer. Sifting removes lumps and separates grains of sugar so they are easily dissolved in the small amount of liquid used.
Grate lemon rind into sugar.	Sugar separates the moist particles of lemon rind and quickly absorbs lemon flavour.
Separate whites and yolks of eggs. Beat yolks until thick, being careful to scrape down any yolks that may stick to sides of bowl.	Particles of egg yolk will stick to the bowl and dry on it; these may make yellow flakes in cake.
Gradually beat in sugar and grated rind; then add lemon juice and water.	Acid makes egg whites more tender after baking, and a better texture results.
Beat egg whites with a wire beater until stiff, or until they will stay in the bowl when inverted. Do *not* beat them until dry. Lift beater up and out of the egg whites with each stroke.	Beaten egg whites quickly lose their lightness on standing. A wire egg beater makes product lighter than does a Dover beater. If beaten until dry, the albumin walls will be very fragile and will not stand the strain of further beating or the addition of other ingredients.

Cut and fold part of whites into yolks and sugar. Then gradually cut and fold in the flour.	There is not enough liquid in yolk mixture to make a batter of flour; consequently a part of egg whites must be added before any flour is added.
Cut and fold in rest of egg whites. Do not stir or beat.	By adding a part of egg whites at the last, greater lightness of product is insured.
Put in ungreased pan. Bake immediately in slow oven (300°F.) for 1 to 1½ hours. (See general directions for baking unshortened cakes.)	By leaving pan ungreased a surface is furnished to which cake will cling as it rises, thus helping it both to rise and to keep its shape.

Angel Food Cake.

Equipment.

1 platter or large bowl	1 flour sifter
1 cup	1 egg whip
1 teaspoon	1 tablespoon
1 rolling pin	1 angel food cake pan

Materials.

1 c. or 9 egg whites	¾ c. sugar
¼ t. salt	¾ t. vanilla
¾ t. cream of tartar	¾ c. flour

Amount: 1 cake 9in. in diameter.

Method.

How.	*Why.*
Roll, sift and measure sugar. Sift flour and measure lightly, being careful not to pack. Sift again 4 or 5 times.	(See *General Method.*)
Pour egg whites on a large platter or bowl, add salt, and beat with a flat wire egg beater until foamy.	A flat wire egg beater will incorporate more air in egg whites than will a Dover egg beater.
Add cream of tartar and continue beating until eggs are stiff but not dry.	Cream of tartar seems to make cake whiter and prevents its shrinking while baking.
Gradually fold in sugar, add flavouring, then gradually fold in flour. Use as few motions as possible by making each one count.	Too many motions may remove most of air from cake; if not enough motions are made, cake may be coarse-grained.
Pour in ungreased pan and bake in slow oven (300°F.) 1 to 1½ hours.	

Kisses.

Equipment.

1 mixing bowl	1 measuring cup
1 egg whip	2 teaspoons
Baking pan or board	

Materials.

2 egg whites	½ c. fine granulated sugar
¼ t. vanilla	

Amount: 2 dozen 1½in. in diameter.

Method.

How.	*Why.*
Beat egg whites until stiff but not dry.	(See *General Method.*)
Add half the sugar and beat.	The albumin walls are not strong enough to hold the entire amount of sugar at once. The water in the egg whites tends to dissolve the sugar as the eggs are beaten. If all the sugar were added at once, a syrup would form and product would be sticky rather than light.
Beat until mixture will hold its shape.	The dissolved sugar must be thoroughly blended with egg whites.
Cut and fold in remaining sugar and add flavouring.	By folding in half the sugar at the last, the sugar does not have a chance to dissolve before product is baked.
Shape with spoon or pastry bag on wet board covered with oiled paper. If board is not available, use bottom of baking pan covered with oiled paper. Bake in slow oven (300°F.) 15 to 20 minutes.	Because the albumin of egg white cooks very easily, it is necessary to protect this product from too much heat. A board does not hold heat as does a tin mould; and if wet, will not become scorched or burned in the oven.

(*To be continued.*)

[Next month's issue will deal with Frostings and Fillings.]

NELSHABY (Average Annual Rainfall, 17in.).

June 26th.—Attendance 33.

The evening took the form of a competition of pastry and needlework, the former three samples of each of four varieties of pastry, the latter a pair of pyjamas for night wear. Mrs. Orchard of the Belalie Branch acted as judge and gave a short paper on needlework. Mrs. R. P. Noble was awarded first prize for pyjamas, Miss I. Franks second. The first prize for pastry went to Miss A. Lawrie, whilst Miss E. Franks took second in that division. A short musical programme was given. (Secretary, Mrs. T. Franks.)

PARRAKIE (Average annual rainfall, 14.64in.).

June 26th.—Attendance, 14.

Papers read by Mrs. Lahne and Miss Hamilton on "Dairying Methods".—(*Mrs. Lahne*): "I think the Shorthorn the most profitable cow to keep. Some prefer the Jersey cow, but they are too delicate. The Jersey does not do so well on dry feed as other breeds of cows. They are a very good breed but need a lot of greenfeed, and are only suitable for districts where there is an abundance of green fodder. They also feel the cold weather more than other cows, and thus need a lot of shelter. The Shorthorn is a hardier breed. I have a crossbred cow that is 13 years old and still gives a good quantity of milk. I feed my cows twice a day, giving them a tub full of chaff and plenty of bran for each meal. One of the main points of dairying is to milk at regular hours. The next point is cleanliness. The cowyards and sheds should be kept as clean as possible; the floors should be cemented, and sloping so they can be hosed down. Wash the cow's udders before milking, preferably in a weak solution of Condys, otherwise use warm water. See that buckets are quite clean. They should be well washed with a little washing soda in the water, then scalded and put to air. The same applies to the separator. It must be taken great care of and kept very clean. When separating, the cream should be cooled as quickly as possible and kept at a low temperature. Stir the cream daily. Deliver cream as often as possible to the factory for best results."

(*Miss Hamilton*): "Dairying at the present time is not nearly as profitable as it has been for a good many years; butter all over the world is more plentiful and is produced cheaper, and many people are not able to buy and use as much as they would like. In buying a cow we should look for a cow with outstanding eyes, a brushy tail, square udder, a fine silky skin, and large milk veins. Kindness and gentleness are very necessary in handling a cow, and cleanliness in all things in connection with

dairying is most essential. When milking, brush the side and udder of the cow, wash the teats and dry them. Dry milking is better and cleaner than wetting the teats. To have good cream and butter, keep buckets and all utensils and hands perfectly clean. Buckets and utensils should be washed and scalded and put in the sun. Secure good cows; one good cow does not eat as much as two poor cows and will give just as much butter. It is necessary to have plenty of good food for cows; bran or oats, and chaff is good for dairy cows, salt is also a necessity. A cow should have as much salt as she will consume. As soon as milking is finished, strain the milk and put it through the separator; then the cream should be cooled off as soon as possible. Cream should be about three days old for churning.'' (Secretary, Miss J. Halliday.)

PENOLA (Average annual rainfall, 26.06in.).

June 6th.—Attendance, 41.

Mrs. A. V. Zed, Secretary of the Alsatian Club of South Australia gave a short lecture on Alsatian dogs.

Biscuit competition, judged by Mrs. R. Black: Mrs. Thos. Oswald first, Mrs. W. A. Clifford second, and Mrs. F. J. Kidman third. The judge spoke highly of all entries.

Biscuit Recipes.—*Plain Biscuits*: 3 cups flour, 1 cup each dripping and sugar, 2 teaspoons cream of tartar, 1 teaspoon each soda and salt. Beat dripping and sugar, add ½ cup of milk, then flour with cream of tartar and soda mixed in. Roll fairly thin and bake in moderate oven for 10 minutes. *Champagne Biscuits*: 2 cups flour, ¼lb. dripping, 1 cup sugar, 1 teaspoon cream tartar, ½ teaspoon soda, 1 egg, 1 tablespoon milk. Beat egg and sugar together, add milk, rub dripping in flour, mix into a stiff dough, bake 10 minutes. *Raspberry Wafers*: 2 cups flour, 1 cup sugar, ½lb. dripping or butter, ½ teaspoon cream tartar, ¼ teaspoon bicarb. soda, ½ cup milk. Roll out as thin as possible. Cut and bake in a quick oven 5 to 10 minutes. Ice and spread jam between. *Oatmeal Biscuits*: 2 cups plain flour, 1 cup each oatmeal, sugar, and dripping, pinch salt, 1 teaspoon cream tartar, ½ teaspoon bicarb. soda, ½ cup milk. Cream dripping and sugar, rub in flour and cream tartar and soda. Mix with the milk, bake in moderate oven 15 minutes. *Hot Water Biscuits*: 3 cups flour, 1 cup each dripping, sugar, and hot water, 1 teaspoon each cream tartar and bicarb. soda. Rub flour, sugar, and dripping, then add cream tartar, and bicarb. soda. Bake 20 minutes. *Cinnamon Biscuits*: 2 cups flour, ¼lb. dripping or butter, 1 cup sugar, ½ teaspoon b. soda, 1 tea-

spoon c. tartar. Rub butter into flour, with 1 teaspoon each cinnamon and allspice, mix with ½ cup milk, roll out and bake in moderate oven 15 minutes. *Light Biscuits*: ½lb. butter, 1lb. flour, 1 cup sugar, 1 teaspoon cream of tartar, ½ of soda, 2 eggs, roll out thin, bake in brisk oven, put two together with jam. *Shortbread Biscuits*: Take ¼lb. each butter and sugar, a good ½lb. S.R. flour, 1 egg, a little essence. Cream butter and sugar, then add flour, egg, and essence until a nice soft dough. This is suitable for forcer. *Potato Biscuits*: Prepare 1½ cups of hot mashed potatoes, measure ¾ cup butter, ½ cup each golden syrup and treacle into a saucepan, stir over fire until melted, then add potatoes. Remove from fire and stir in 2 cups flour, sifted, with ¾ teaspoon ground cinnamon, ½ teaspoon each grated nutmeg, ground clovers, and c. soda, 2 teaspoons baking powder, add ½ cup chopped dates and ½ raisins. Drop in teaspoonfuls on greased baking slide. *Parkin Biscuits*: 4ozs. flour, 4ozs. oatmeal, 2ozs. lard, pinch of salt, one flat teaspoon baking powder, 1 of mixed spice, 2 tablespoons brown sugar, 2 tablespoons of treacle, almond kernels. Sift the flour with the salt and baking powder and spice, then add the oatmeal. Put the sugar, lard, and treacle into a saucepan and heat slowly until melted. Stir in dry ingredients and mix well. Take small pieces and form into balls, put ½ an almond kernel on each, bake until crisp and firm—about 15 minutes. *Coffee Kisses*: 4ozs. butter, ½lb. S.R. flour, 3ozs. castor sugar, 1 egg, 1 tablespoon coffee essence, pinch of salt. Beat butter and sugar to a cream, add coffee essence. Sieve flour and salt, beat egg, add flour and egg alternately to the mixture. Place two together with filling: 3ozs. icing sugar beaten well together with 1½ozs. melted butter and 1 teaspoon coffee essence. Dust with icing sugar.

RENDELSHAM.

July 4th.—Attendance, 12.

KNITTING HINTS.—Paper read by Miss P. Foster:—"To knit a garment and make a success of it good wool is essential; it is lighter and goes further than cheap wool, A good light wool is preferable for all babies' clothes, underwear, and light summer jumpers (I prefer Patons 2-ply for these), but for a warmer jumper 3- or 4-ply wool will be found more suitable. For socks that have to stand hard wear, choose a good heavy wool. Never wind wool tightly, it destroys the elasticity and lustre. After having cast on stitches, if a firm edge is required knit into the back of the stitches for the first row. Do not knit too tightly, or when the article is washed it will shrink quickly, just keep the stitches on the needle to allow them to slide easily. Always knit to the end of a row before putting work away. Some knitters leave off in the middle of a row in order to fold the needles with the work, but this has a tendency to show unevenness in the finished article. Do not run needle in and out of work. Cast off stitches on wrong side of work. This makes a firmer edge." (Acting Secretary, Miss P. Foster.)

SADDLEWORTH (Average annual rainfall, 19.61in.).

June 5th.—Attendance, 9.

BUTTER MAKING.—Paper read by Mrs. Vogt:—"The cows should be given good stall feeding in addition to pasture. They should be fed morning and night, bran with chaff prevents butter being tainted by weeds and imparts a good flavour. All dairy utensils must be kept carefully clean with soda washes (not too hot) and rinsed in scalding water. A sunbath for separator, milk buckets, cream cans, and churn—after being washed—is an excellent germ killer and sweetener. Care must be observed to cool cream quickly after each separating, and never to mix warm cream with cold. All cream should be cool; under a draughty verandah is ideal for the winter and summer nights. It is most necessary to prevent the rays of the sun from striking cans containing cream. Cream should be made into butter while fresh—allowing for weather conditions—three or four times a week. Fairly thick cream gives best results. Put salt with cream into churn, 1lb. of salt to every 10lbs. of butter—of course, salting is a matter of taste—work it until it reaches the crumbly stage, add 1gall. or so of cold water, never warm, work again until butter milk runs off the shiny surfaces of the solid mass of butter. Pour off the butter milk and pour cold water on the butter, pressing and stirring well. Strain off the milky water, repeat until water pours off clear. If milky particles are left butter will be streaky and will not keep well. Leave butter stand 12 hours. Press out all the water. The butter is then weighed into pounds, pressed well into shape, and neatly covered with butter paper. Allow 1oz. to every pound of butter for shrinkage. An easy way to cover butter with paper smoothly is to dip butter papers in cold water before wrapping."

REARING OF CALVES AND A FEW POINTS ON DAIRYING.—Paper by Miss D. Coleman:—"*Care of the Calf*: The calf is usually able to stand soon after birth and able to drink from its mother, the best practice is to leave it with its mother for about 24 hours, the calf should then have the colostrum—the first of its mother's milk. *Calf Housing*: The sheds should be warm and dry and yet open to receive sun and fresh air. I

prefer to keep a calf by itself until able to drink from a bucket, which should be within a few days. In a week, calves enjoy a run in a small yard or pasture paddock. *Cleanliness is Essential:* All sheds and yards should be cleaned regularly, kept limed and clean-bedded, and feeding buckets washed. Scours, the most common disease with calves, is generally caused by uncleanliness or cold or overfed with milk. An efficient remedy for a severe attack of scours is 1 beaten egg in a little warm milk, 1 may be enough, if not, repeat 12-hourly until the calf is better, no other milk should be given. Calves with this complaint should be kept by themselves or other calves may develop it. *Feeding:* Milk fed to calves should be heated to 98° F. It is much better to give a calf a little milk often than a lot at once. 6lbs. to 9lbs. daily for the first week and then increase gradually; 15lbs. a day is enough for a Jersey calf, other breeds with bigger calves could take more. Feed for about 3 weeks on whole milk—its own mother's for preference—and then gradually change to separator. At 3 to 4 weeks a calf will eat grain, chaff, and hay; feed a little in a box, also they will take a salt lick, which helps to keep them healthy; equal parts of salt and bonemeal or salt and super. At 3 to 4 months the calves are old enough to go out into a paddock if good pasture is available. If milk is plentiful, feed calves once a day with 1gall. of milk until about 5 months old. If possible, handle the calves to quieten them, and they will be easier to handle later. *A Few Hints on Dairying:* To receive the best from the cows, handle kindly and quietly, milk regularly, and always strip dry, give a change of paddock and feed when possible and always provide plenty of fresh drinking water. The two most common diseases are milk fever and mammitis. The usual practice for milk fever is to inflate the udder with air, and this way the cow should be on her feet in a few hours. Mammitis is a disease in the udder, and the germs seem to be always present. Always be careful that the udder and the milker's hands are clean. If there is ever any inflammation this treatment is very satisfactory—Bathe with hot water which contains disinfectant, rub well to dry it, and then rub well into the udder equal parts of olive oil and kerosene, and strip the quarters dry. Cows should have shelter, especially in this district, from cold east winds." (Secretary, Miss G. Frost.)

STOCKING THE MEDICINE CUPBOARD.—Mrs. Hill read the following paper:—"A few simple remedies needed to-day for first aid take up very little room, for they can all be bought ready made and only need a cupboard with a lock and key and a tin for storing a few dressings. The contents of the cupboard should be clearly labelled and any which are of a poisonous nature should have a label to that effect. Have a list of the contents pasted on the inside of the door so that no time is lost looking for something which is not there, and in case of an accident it is not easy to think just what you have in stock. When the last of any of the medicines, &c., is used, obtain a fresh supply before it is forgotten or it is sure to be the very thing that will be needed next. Tincture of iodine is such a substance, and it should be the routine treatment in every home that any cuts, scratches, splinters, or if a nail is trodden on and pierces the flesh, should have a dab of iodine at once. If the skin is broken a bandage is advisable to keep out the dirt and germs. Kerosene is also useful towards preventing any septic condition. Peroxide diluted with water makes an excellent mouthwash, and is also antiseptic for cuts or wounds. Lysol made into a weak solution should be used for washing the thermometer in all cases of sickness, more particularly in contagious diseases. Boracic crystals make an excellent eye lotion and are more easily dissolved than the powder. Castor oil, olive oil, and eucalyptus should all have a place in the chest, as they are all needed in case of colds in the head. Friar's balsam used as an inhalation —1 teaspoon to 1 pint of boiling water—is splendid for a cold on the chest. Ammoniated tincture of quinine often checks a cold. Brandy is also necessary; it is one of the quickest cures used as a gargle for a sore throat and is also handy in cases of fainting. Aspirin tablets should not be taken on the slightest provocation, as the drug from which they are made is a strong one, but it is better to take two aspirin tablets than be racked with a headache. Carbonate of soda is splendid for hot foments; 1 teaspoon to 1 pint of boiling water I found it most effective in a case of severe sunburn when the legs were badly burned and swollen. Epsom salts, seidlitz powders, and cascara tablets, should all be included in the chest. A lemon squeezed into a cup of black coffee will often cure a bilious attack and is worth trying." (Secretary, Mrs. A. Cundy.)

THE JOURNAL

OF THE

Department of Agriculture

OF SOUTH AUSTRALIA.

VOL. XXXVIII. NOVEMBER, 1934. No. 4.

Published Monthly by the Department of Agriculture.

Edited by H. C. PRITCHARD.

CONTENTS.

All communications to be addressed:

"The Editor, Journal of Agriculture, Education Building, Adelaide."

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

River Murray Swamp Areas, at Murray Bridge (Jervois Branch), Thursday, February 21st (F. P. Baily, Woods Point, Secretary).

Mid-North, at Redhill, Thursday, March 14th (S. A. Pengilly, Secretary).

South-East (Upper), at Mundalla, Wednesday, March 20th (A. Ross, Secretary).

South-East (Lower), at Mount Gambier, Wednesday, April 10th (G. T. Gurry), Secretary).

River Murray, at Moorook, Thursday, June 20th (S. Perkins, Secretary).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Trade with India.

The Department of Commerce has drawn attention to statistics which reveal the fact that Australia's export trade to India is steadily declining. The position may be summarised briefly to the effect that, whilst India is continuing to find an increasing market for her goods in Australia, she is buying less and less of Australia's products each year, and in consequence the adverse trade balance against Australia is steadily mounting. If, with the decline in total exports, there were a decline in practically all the commodities which go to make up that total export trade, the search for the cause would be simplified; but it is found that in many of the commodities which we export our trade has actually improved. A comprehensive statement is drawn up setting out the commodities which show an increase in the export trade to India and those showing a decrease. Amongst the former are cheese, milk and cream, fodders, dried fruits, fresh fruits, canned fruits, flour, jams, other vegetable foodstuffs, wine, other alcoholic liquors, animals (other than horses), and wool. Some of the commodities showing a decrease are butter, bacon and ham, meat, other animal foodstuffs, preserved meats, fruit juices, wheat, ales and horses.

One of the difficulties which is being quoted by exporters generally is the fact that the ports of Madras, Calcutta, and Rangoon, which are the spearheads of large areas of consumption, are not in direct communication with Australia. Transhipment at either Colombo or Singapore adds to the landed cost of the goods at the ports mentioned. In the case of refrigerated cargo the transhipment difficulty is the big hindrance to trade progress from Australia, and furthermore the extra handling and storage whilst awaiting the on-carrying steamer leaves the goods open to pilferage and deterioration as well as to many other difficulties.

United Kingdom exporters enjoy certain tariff preferences in India over Australian exporters, but as Australia is continuing to buy and is even increasing her purchases of Indian goods, we certainly have a good basis to any case which might be presented to the Indian Government for an extension of those preferences to Australia.

Included in the statistics are comments regarding the States of the Commonwealth supplying the Australian trade in the commodities quoted. The eastern States supply most of the Australian commodities and South Australia appears only to be mentioned in its trade in wine of which our exports to India in 1932-33 were 1,162galls. of a total imports to India of 165,370galls. Our trade for that year was, however, over 100 per cent. greater than for the previous year.

Rickets in Pigs.

The Secretary of the Stockport Branch of the Agricultural Bureau reports that several members of the branch have young pigs with mis-shaped joints and unable to stand. Mr. A. H. Robin, B.V.Sc., of the Stock and Brands Department says the

trouble undoubtedly appears to be rickets. This disease is caused through an insufficiency of minerals, particularly calcium (or lime). To prevent its occurrence, the young pigs—from weaning onwards—should be given at least ½gall. of separated or skim milk per head daily. Failing this, they should be supplied with the following mineral supplement mixture:—Agricultural (or air-slaked) lime, 2 parts, common salt, ½ part. This mixture should be added to the diet at the rate of 2½ per cent. of concentrates fed. The pigs should also be given a daily run on green pasture or a daily allowance of fresh cut green feed in the ration. Affected animals should be placed in clean warm sties, where they can be well exposed to direct sunlight and in addition to feeding them on a diet of cereals, milk (or mineral supplement) and green feed, they should be given each 1 teaspoon of cod liver oil (of guaranteed quality) twice daily.

Important Notice to Stockowners.—Cancellation of Registered Brands and Marks.

The Registrar of Brands (Mr. H. O. Laurenti) desires to remind stockowners that in order to retain their existing brands they must apply to the Registrar of Brands, Adelaide, setting out full particulars as to name and address, Hundred in which the brands are being used, and particulars of all the brands and marks registered in their names. There is no fee charged for the retention of the brands, but persons requiring an acknowledgment from the Registrar must enclose a stamped addressed envelope. The reason for giving this special reminder is that the time expires on the 31st of December, 1934, and should any person fail to apply by that time the brands registered in his or her name will be cancelled. Readers are requested to acquaint others of the above notification.

Ensilage and Grass Hay Competitions, 1934.

The South Australian committee of the Australian Dairy Council, in conjunction with the Department of Agriculture, is again promoting Ensilage and Grass Hay Competitions amongst the dairymen in this State. Dairymen are urged to enter for these Competitions, as it is the spirit of healthy competition which improves the standard of our primary products. The improvement of the pastures of the State means the improvement of our dairy herds and the produce therefrom. Entries are invited from dairy farmers in two districts, namely, Hills and South-Eastern, and are restricted to those dairymen who are milking not less than seven cows. Trophies and certificates are to be awarded in each of the four competitions, and successful competitors will receive prizes as under:—First, £3 3s. and certificate; second, £2 2s. and certificate; third, £1 1s. and certificate. Entries will close on January 5th, 1935, and the entrance fee is one shilling. Entry forms and further particulars regarding these Competitions may be obtained from the Secretary, c/o Office of Minister of Agriculture, Flinders Street, Adelaide.

Fat Lambs for the Williamstown District.

Replying to a subscriber to the *Journal of Agriculture*, who asked what is the best cross for fat lambs for the Williamstown district, Mr. W. J. Spafford (Deputy Director of Agriculture) says large-framed Corriedale ewes, or well-grown Comeback ewes, mated to Southdown rams would produce fat lambs of the very best quality at Williamstown, and the ewes would cut a fairly heavy fleece of high value in that district. To produce fat lambs from Merino ewes the Southdown will probably prove the best breed of sire to use, producing a high percentage of lambs, all of which will become marketable, and with the minimum of lambing trouble, even if the Merino ewes are on the small side. If the pastures have been regularly top-dressed, and particularly if Subterranean Clover is established on an extensive scale, maximum results will probably be obtained from fat-lamb breeding activities if the lambs are dropped early in September. Mating in autumn leads to a much greater percentage of lambs, less lambing trouble, certain green feed for the ewes at lambing time, and a good market for high-class lambs around December, and a little later.

THE CLAIM OF MEN ON THE LAND UPON THE PEOPLE OF AUSTRALIA.

(A National Broadcast Talk delivered on October 18th, 1934, through 5 CL, Adelaide).

[By ARTHUR J. PERKINS, Director of Agriculture.]

The celebration of Victoria's Centenary comes appropriately enough to remind us that the White Race has now been in occupation of the Fifth Continent for more than one hundred years; but it needs a glance extending even further backwards to make us realise that 145 years ago the first crop of Wheat ever grown in Australia was being harvested at Parramatta in 1789; that is to say, that the first Wheat Crop of Australia was contemporaneous of the sack of the Bastille and the outbreak of the French Revolution. Eight years later, in 1797, Merino Sheep from the Cape of Good Hope were first introduced into New South Wales. And it is upon these two corner stones—Wheat and Wool—around which in due course other rural undertakings and mining came gradually to cluster, that has in the main been progressively erected the imposing superstructure of the present-day National Wealth of the Commonwealth. May I state here that I realise to the full the inappropriateness, and indeed the usual futility of an array of figures in Broadcasted Addresses; and I am well resolved to-night to give figures as wide a berth as circumstances permit. Hence, I regret the necessity of having to support these opening remarks with a few numerical data.

The Commonwealth Statistician has estimated that the *private* wealth of Australia at June 30th, 1929, exceeded 3,351 millions sterling, and corresponded to £526 per head of population; but in this huge sum has not been included communal Wealth vested in the property of Commonwealth and State Governments and of Local Governing Bodies. By way of contrast it should be noted that 116 years earlier, in 1813, it was estimated that the Private Wealth of Australia did not exceed one million sterling, or £75 per head of population only.

If I have stated that this National Wealth of ours rested upon a solid foundation of primary production, I did not mean to infer that primary production was the exclusive source from which our Wealth had been derived; something we undoubtedly owed to our Captains of Industry and to the thews and sinews of a rapidly expanding industrial population; but since hitherto we have been unable to export more than 3 per cent. of our manufactured commodities, to no appreciably greater extent than the relatively modest personal requirements of six and a half million people. Contrast this figure with our normal export of nearly one-half of the Primary Products raised in Australia; from this aspect alone the importance of Primary Production to the community should be apparent. Nor should the auxiliary role played by Capital borrowed from abroad be overlooked; it is this money which in our impecunious past had rendered possible the progressive opening up and development of new country, the building and equipment of harbours and railroads, the construction of roads and bridges, adequate provision for water requirements of a rapidly expanding population, and many other items that are inseparable from the settlement of virgin country, and bringing it into profit. Hence, it would probably be no exaggeration to say that had it not been for the services rendered in the past by the Capital corresponding to our External Debt of 600 millions sterling, we should probably to-day be no further advanced from the political or economic standpoint than were our fathers towards the middle of last century.

This brings us to the second role which primary production has been called upon to play in the Commonwealth. Its first role has been shown to be the progressive building-up of wealth; and the second is now seen to be the provision of the medium by means of which alone can be paid interest due on money borrowed abroad in the main for the development, and more recently, for the defence, of Australia; and occasionally perhaps for less commendable purposes. Such interest, of course, can be met by the transfer of gold abroad; but the amount of precious metal available at any given time is not inexhaustible; and eventually most of the interest due has been liquidated from credit created abroad by the sale of exportable home commodities. And since the value of Exported Primary Products is usually represented by 97 per cent. of the value of Total Exports, whilst that of exported manufactured commodities does not exceed 3 per cent., the value of Primary Production to the community in this direction cannot be over-stated.

In the circumstances that have been indicated one would have imagined that Primary Production would have occupied a major position in the thoughts and actions of the people of Australia; that nothing would have been done to disturb the rhythm of its progress, but rather that everything would have been done to intensify its output and well-being. And such indeed appeared to be our general mental attitude some thirty or forty years ago; we were in those days still nationally conscious of our dependence upon the men on the Land, and our thoughts and actions were coloured accordingly. But a subtle change has crept over our outlook during the past thirty odd years; we are no longer *Colonists*, but independent nationals of a vast but thinly populated Continent; and if in our midst a few Colonists should still survive they will surely be found among those lonely individuals who invade our Metropolitan Areas at Show Time; of whose scheme of life we know little, and care less, so long as they meekly supply the foodstuffs we require, and the pressing export needs of our national economy. It is surely significant that even candidates for country Parliamentary honours no longer think it necessary to remind their prospective constituents that the latter are the backbone of the State. The fact of the matter is that as a community we have to all intents and purposes lost the pioneering or frontier spirit; we have become overwhelmingly urbanised, and are in danger of adopting the traditional procedure of living upon the country rather than for the country. I suggest that self-interest, if no higher motive, should cause us to pause and consider whether our individual welfare, and that of the community of which we form part, is not dependent upon the technical and financial success of the Men on the Land; and if so much be granted, whether our national economic structure would not be in danger of complete collapse if, through no fault of their own, nor of their immediate environment, these Men on the Land should eventually be driven off their holdings. And in such circumstances, what should we think of our personal responsibilities when we came to realise that this calamity, should it eventuate, would be no more than the natural consequence of that mistaken policy which, during the past thirty years or so, has sought to force industrial self-sufficiency upon a country hardly yet emerged from virgin wilderness, and wholly dependent upon primary production for its solvency.

Briefly speaking, the position may perhaps best be summarised as follows:—Primary Production is compelled to sell its commodities upon the Markets of the World, or to accept for them export parity on a limited home market; that is to say, usually in the cheapest markets. Hence it follows that for business success its necessary purchases should also be made in the cheapest markets, or else certain failure must ensue. And this unfortunately is what has been happening to our Primary Producers who have been compelled to sell in the cheapest market, but to buy on a highly protected home market, the dearness of which has been progressively rising from the earliest days of Federation. And this sad abnegation

of all sound business principles can have but one eventual end—and that an end that no other policy could compass—namely, the progressive "starving off the land" of primary producers.

Nevertheless, notwithstanding the manifest absurdity of our national policy when brought to bear upon our natural conditions, I recognise that not without considerable hurt to the body politic would it be possible to pass abruptly from extreme protectionism to that freedom of trade under which alone Primary Production can be expected to thrive. But with the possible exception of what might be considered to be "key" or "national" industries, there is little to hinder progressive scaling down of most of our tariff charges to a reasonable basis of revenue production, which after all was the original function of all tariffs. Nor in this connection might it even be necessary to give special consideration to these so-called "national" industries; for it does not necessarily follow that present inability to meet overseas competition on even terms will hold good after the tariff barriers have been lowered, and slumbering local industries whipped into undreamt efficiency by keen overseas competition. Many industries, no doubt, will ultimately give way before more efficient competitors; but the community as a whole will benefit from the change. Others, again, in the opinion of many competent observers, will not only be able to retain their hold of the home market, but, in addition, will so improve their technique as ultimately to be able to meet successfully the competition of allcomers on the accessible markets of the World.

The ultimate re-actions that may be anticipated from a policy of this kind may be summarised as follows:—Progressive improvement in the quality of manufactured articles placed on the Australian market, coupled with progressive decline in prices; corresponding reduction in cost of living, to which, again, would correspond reduction in costs of production of all efficient secondary industries in the first place, and ultimately in all forms of primary production as well; and this, I take it, is the goal that every country largely dependent upon primary production should ever keep steadily in view. True, such a policy would probably lead to a reduction in the apparent value of Wages paid, but this reduction would have been more than met by prior reduction in the cost of Living and by increased purchasing power of the Wages earned.

But the full benefits of such a policy would not become apparent until the lapse of several years; and, moreover, although in my opinion it is the only policy that adapts itself logically to the economic conditions of a country such as Australia, it has not hitherto found favour in the eyes of those able to dictate in such matters; nor does it appear likely to do so in the near future. And in the meanwhile the Man on the Land goes on from precarious year to precarious year, and manages to retain a grip of his holding by reducing his standard of living to a vanishing minimum, and by the compulsory grace of his creditors.

In the meanwhile, therefore, something must be done if we wish to forestall a regrettable catastrophe; and because I believe that in this country, above the political machine, above the press, above all sectional combinations, *Public Opinion* is still supreme, I make special appeal to the Man in the Street on behalf of the Man on the Land; not because he is "the backbone of the State," not because he is the prime builder of our national wealth and we cannot do without him, but because in the majority of cases he finds himself in distress, which was not caused but intensified by four seasons of low World prices; nor can he be helped out of his difficulties except by the grace and goodwill of the people.

Such assistance as has hitherto been given to Rural Industries has usually taken the shape of grants-in-aid or Bounties, with the striking exception of Dried Fruit, and more recently, but temporarily only, of Dairy Products. The chief objection to the former when applied to old and well-established national industries is that they savour too much of patronage and charity. It may be well enough for insecure Iron and Steel Industries not to boggle at Bounties, even from behind the

efficiency of high tariff walls, but when doled out to Wheat they seem to confer dignity neither upon the donor nor the recipient. The fact that should in this connection be kept clearly in our minds is that had it not been for Federal obsession over high tariffs, the abnormally high costs of production that have critically hampered rural producers of recent years would not have obtained, and not even recent World prices would have been considered wholly unremunerative; hence it would be no more than seemly that whatever assistance were given should come as a matter of natural right, rather than in the form of a dole, however weighty. The difficulty, no doubt, will be how to devise means leading to results that would prove acceptable to all concerned; but if none were forthcoming, we might perforce have to swallow our pride, and accept the dole, however distasteful.

One suggestion, however, may perhaps be made, not because of its originality, since it has frequently been debated in country circles, but because of its simplicity and apparent logicalness. It is to the effect that so long as a sheltered home market, and corresponding home prices, were provided in Australia for secondary industries, with their consequential influence on the costs of production of Primary Industries, it is no more than logically just that corresponding home prices should be allowed for such portion of our rural products as are consumed within Australia. If such be granted, then the relatively high home prices and the relatively low World parity prices would in combination supply Australian Rural Producers with mean prices approaching costs of production more effectively than has latterly been the case; provided that adequate provision were made for equalisation between States with heavy export and low consumption percentages on the one hand, and States with low export and high consumption percentages on the other. An arrangement of this kind has been in force for the Dried Fruit Industry since 1924, and may be said to have rendered possible at a critical moment in our rural history the progressive but effective development of a

remunerative export trade, and to have saved thousands of pounds invested in our River Colonies. Quite recently, too, the same principle has been extended to the marketing of Butter and Cheese, but for one year only; and it is hoped that it will do much towards extricating our Dairymen from a perilous economic position.

I do not suggest that this proposed manipulation of price values in defiance of the Law of Supply and Demand offers an ideal solution of our problem; nevertheless, in a World and in a Period in which "national self-sufficiency" in everything seems to be the only principle upon which all Nations appear to be in complete agreement, I can see no alternative, or perhaps none better. During 34 years of Federation we have shown grim determination to exact from our citizens prices considerably above export parity values for the unexportable output of our factories; we have chosen, too, to shut our eyes to the crippling influence of such a policy upon rural production in general; and now that rural production can no longer make ends meet on the basis of export parity prices for its output, we cannot, in common fairness, refuse to that fractional portion of rural production that is consumed at home the same consideration which we have been extending to the unexportable output of our factories for the past 34 years.

True, it will be said that to raise the cost of Foodstuffs would have the effect of raising the cost of Living, and this, no doubt, is true; but so does every single tariff charge on the Statute Book, and to the latter no exception appears to have been taken; that these enhanced home prices would be felt most severely by the poorer classes of the community; and this, too, would be true but for the fact that the machinery of our Courts of Justice watches over the welfare of those in receipt of minimum basic or award wages which are made to fluctuate with corresponding aggregate fluctuations of the necessaries of Life, of which Foodstuffs obviously form a large part.

But it is obvious that should inclusive Legislation on these lines ever be contemplated, opposition of the bitterest kind may have to be overcome; and, as in all such matters, the final decision will rest with instructed Public Opinion. Hence, I make a final appeal to the Man in the Street, to consumers generally, and in particular to thrifty Housewives, upon whom the burden of keeping the larder replenished necessarily falls. To these I would say:—

> Would you feel comfortable if you knew that the garments you purchased were the products of unregulated sweated Labor? And, if not, is there any moral difference between the prices paid for the products of unregulated sweated Labor on the one hand, and prices paid for Butter, Milk, Wheat, &c., which do not bring in sufficient money to pay for the cost of producing these Commodities, on the other hand? And, finally, is it morally indefensible to sweat the cottage worker, or to under-pay factory hands, but permissible to sweat the rural worker?

I do not propose saying more than that; the replies to these questions must be left to the consciences and common-sense of the people of Australia.

In conclusion, I shall state that I have tried to show that the Men on the Land had a strong moral claim upon the People of Australia, in the first place because they were responsible for national work of first-rate importance, and in the second, because indirectly the National Policy of Australia had raised the costs of Production of Rural undertakings beyond the profit limit. These undertakings are exceedingly varied, and it would not therefore be possible to assess this claim in actual figures. This much, however, can be said for average conditions:—

The combined money value of saleable Farm Products, after meeting Costs of Production, including home and hired labor, apart from that of the owner, necessary purchases, rates and taxes, interest and depreciation, should leave a Balance sufficient to yield to the owner a Labor Income equivalent to not less than the wages of a skilled artisan.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

FORTY-FIFTH ANNUAL CONGRESS.

OPENED BY THE GOVERNOR.

The 45th Annual Congress was held in the Way Hall, Adelaide, on Monday, Tuesday, and Wednesday, October 8th, 9th, and 10th.

DELEGATES.

The following branches appointed delegates, and the figures indicate the number of sessions for which attendances of delegates were recorded:—*Adelaide*—J. Y. Hudd (2), J. R. Newland (5). *Alawoona.*—W. Paull (3), A. J. Pengilly (5). *Allandale East*—F. W. Thompson (4), R. T. Laslett (5). *Angaston*—W. Giles (1), W. Sibley (2). *Arthurton*—D. Noble (3), P. Ford (3). *Balaklava*—A. F. Smart (6), H. Wills (4). *Balhannah*—H. Rollbusch (5), R. James (1). *Balumbah*—A. A. Jericho (5), S. G. Jericho (4). *Beetaloo Valley*—P. Curtin (0), B. W. Giddings (4). *Berri*—E. J. Johnson (4), A. G. Jarvis (2). *Black Springs*—J. M. Howard (4), B. Heinrich (5). *Blackwood*—J. Turner (1), H. Goldsack (1). *Blyth*—H. E. Zweck (4). *Booborowie*—A. T. Fairchild (6), W. Kain (3). *Boolgun*—N. Koehne (0). *Boor's Plains*—T. Rodda (3), A. N. Reid (2). *Borrika*—R. G. Bonython (4), H. Griffiths (0). *Brownlow*—N. Woithe (0), A. Steinborner (0). *Buchanan*—W. G. Hucks (0), F. C. Rohde (4). *Bute*—E. H. Ebsary (5), T. Trengove (2). *Butler*—N. G. Stewart (0), G. H. Turner (0). *Calca*—P. C. Roberts (4), J. Harris (3). *Caliph*—W. H. Todd (3). *Chandada*—J. Travers (4), R. J. Mudge (3). *Chilpuddie Rock*—H. Frost (0), F. Herde (4). *Clarendon*—M. Harper (0), T. B. Brooks (3). *Coomandook*—F. E. Ballard (5), W. R. Trestrail (3). *Coonawarra*—W. L. Redman (3), E. G. Allder (5). *Cummins*—M. A. Palm (5), K. A. Trigg (5). *Cungena*—A. Voumard (0), C. Ayliffe (4). *Echunga*—C. B. Symon (4), L. W. Sando (3). *Eurelia*—M. T. Wall (3). *Finnis*—M. Llewellyn (0). *Frayville*—E. Hein (3), V. H. Dohnt (0). *Gladstone*—G. M. Black (5), L. G. Sargent (4). *Goode*—E. H. Fear (5), J. Kelly (6). *Greenock*—C. M. Roenfeldt (5). *Hanson*—W. Woolacott (5), F. Turner (6). *Inman Valley*—A. M. Fuller (0), H. V. Lewis (0). *Jervois*—M. Wilkin (6), W. Gale (0). *Kalangadoo*—H. V. Dowdell (0), R. G. Messenger (0). *Kanni*—C. Schulze (4), A. J. Pobke (4). *Keith*—A. M. Densley (4), L. H. Densley (4). *Kelly*—J. F. Hannan (4), J. W. Parsons (2). *Ki Ki*—R. C. Cooley (3), W. Goodall (5). *Kilkerran*—E. T. Koch (6). *Koolunga*—A. Buchanan (0), J. W. Sykes (0). *Koonunga*—C. B. Mibus (4), B. J. Mickan (4). *Koppio*—B. Low (0), R. Richardson (4). *Kyancutta*—F. E. Daniel (5), R. J Holman (5). *Kybybolite*—J. D. McAuliffe (3). *Lameroo*—E. A. Blake (4), A. G. Potter (0). *Laura*—L. Mudge (2), E. Klemm (0). *Laura Bay*—P. S. Morrison (5), W. Bowell (3). *Light's Pass*—B. Boehm (4), A. J. Summers (4). *Lone Pine*—F. Fromm (5), S. Turnbull (5). *Lyndoch*—E. Evans (4). *MacGillivray*—J. N. Wood (3). *Mangalo*—D. Munday (3), W. Munday (3). *Marama*—A. Rogers (5), T. Hinkley (5). *McLaren Flat*—W. Mobsby (3), P. T. Wait (0). *Millicent*—C. G. Skeer (4), G. Major (4). *Miltalie*—H. R. Jacobs (1), G. E. Smith (0). *Minnipa*—D. Kitto (3), H. E. Broad (3). *Monarto South*—E. Rolland (4), O. Aesche (0). *Moorlands*—A. Mann (5), A. E. Stock (5). *Moorook*—S. Perkins (4), S. Loxton (3). *Morchard*—A. McCallum (4), E. Tilbrook (3). *Mount Barker*—L. Frame (0), H. Hunt (2). *Mount Bryan*—J. R. Simpson (4), H. H. Edwards (3). *Mount Gambier*—A. C. McMillan (5), E. W. Tollner (6). *Mount Hope*—W. F. Vigar (4), J. L. Vigar (4). *Mudamuckla*—A. R. Maguire (5), W. H. Watson (3). *Mundalla*—L. M. Dinning (5). *Murray Bridge*—H. B. Kuchel (2), A. Wells (4). *Murraytown*—

A. J. Clogg (3). *Mypolonga*—P. H. Pickering (0), T. J. Dodd (2), *Nantawarra*—W. Hamdorf (1), T. Dixon (1). *Narridy*—E. W. Richards (4), J. M. Klingner (4). *Nelshaby*—H. Williams (6). *Nunjikompita*—R. Dunn (0). *Nunkeri*—P. J. Oster (1), S. Yelland (0). *O'Loughlin*—C. Bergmann (4), E. Lutz (5). *Overland Corner*—L. Atkinson (0). *Palabie*—G. S. Rashleigh (5), S. H. Rashleigh (5). *Parilla*—A. W. Weldon (4), L. J. Foale (6). *Parilla Well*—E. C. Slater (4), D. Wurfel (5). *Parrakie*—A. Afford (3), G. Hamilton (4). *Paskeville*—S. Pontifex (4), C. K. Stephenson (4). *Penola*—S. Warner (4), F. Hinze (6). *Penwortham*—W. H. Penna (5), J. H. Richardson (5). *Petina*—G. J. Prescott (5), T. L. Schulz (4). *Pinbong*—H. B. Scholz (4), E. M. Scholz (4). *Pinkawillinie*—W. G. Miller (4), S. C. Johnson (0). *Pinnaroo*—A. Gilbert (5), C. H. Ross (6). *Pygery*—W. M. Heath (4), J. Kammermann (0). *Ramco*—G. Watkins (6). *Redhill*—J. V. Dundon (5), H. J. Crouch (0). *Rendelsham*—F. Todd (4), E. Sly (4). *Renmark*—M. B. Geneste (5). *Riverton*—D. C. Hannaford (0), O. E. Longbottom (0). *Roberts and Verran*—S. Barber (6). *Rosedale*—A. H. Wolf (3). *Roseworthy*—J. Dridan (1), J. Carmichael (2). *Saddleworth*—T. Vogt (2), F. W. Coleman (4). *Shoal Bay*—G. Barrett (4), A. Nash (0). *Snowtown*—A. E. Dolling (5), G. T. Freebairn (4). *Stanley Flat*—W. Slattery (4), M. Lee (4). *Stockport*—F. Watts (3). *Strathalbyn*—F. W. Allison (3). *Streaky Bay*—A. W. Cook (0). *Sutherlands*—V. H. Weiss (6), E. Twartz (6). *Tantanoola*—M. Telfer (5), G. H. Bird (4). *Taplan*—W. J. Hammond (4), P. R. Hodge (4). *Taragoro*—J. Crooks (4), E. James (3). *Tarlee*—D. G. Kelly (1), E. T. Clarke (0). *Tatiara*—L. H. Butler (5), F. B. Milne (5). *Tintinara*—H. Bridle (0), E. Bower (4). *Truro*—W. Rice (0), F. Collins (0). *Upper Wakefield*—F. W. Gregor (0), C. Webb (3). *Virginia*—A. Hatcher (6), W. S. King (0). *Wandearah*—W. C. Slater (5), L. C. Crouch (3). *Warcowie*—F. Williams (0), M. Ryan (5). *Warramboo*—F. Chilman (4), J. F. Sampson (3). *Wasleys*—E. Fischer (1). *Watervale*—G. Holder (3), G. W. Baillie (3). *Weavers*—E. H. Giles (3), H. W. Cornish (2). *Wepowie*—H. W. Noske (5), W. G. McGurke (0). *Willowie*—L. K. Wood (4), L. T. Crisp (5). *Wilmington*—P. C. Cole (3), H. H. Carter (5). *Wirrabara*—A. B. Curtis (0), P. Banfield (3). *Wirrilla*—H. Schunke (3). *Wolseley*—M. H. Pilgrim (6), A. J. Grosser (6). *Wudinna*—D. Duguid (5), A. J. Byrne (4). *Yaninee*—W. R. Mitchell (0). *Yantanabie*—N. B. Miller (3). *Yeelanna*—A. L. Carslake (4), J. H. Haarsma (6). *Yurgo*—R. W. Jarrett (6), E. H. Easton (1). *Yundi*—C. Jones (3), G. Lomax (3).

OPENING SESSION.

Congress was opened on Monday evening by His Excellency the Governor, Sir Winston Dugan, K.C.M.G., C.B., D.S.O. Mr. A. J. Cooke (Chairman of the Advisory Board) presided, and there were also present on the platform:—Hon. A. P. Blesing, M.L.C. (Minister of Agriculture), Messrs. F. Coleman, J. B. Murdoch, P. J. Baily, H. N. Wicks, A. J. A. Koch (Members Advisory Board of Agriculture), Professor A. J. Perkins, Messrs. W. J. Spafford, G. Quinn, C. F. Anderson, and R. L. Griffiths (Department of Agriculture), Drs. A. E. V. Richardson and J. Davidson (Waite Research Institute), A. R. Callaghan (Roseworthy Agricultural College), Messrs. W. J. Adey (Director of Education), L. S. Smith (Secretary Minister of Agriculture), W. L. Summers, H. C. Pritchard (General Secretary), and F. C. Richards (Assistant Secretary Agricultural Bureau).

After having been introduced to the audience, His Excellency the Governor (Sir Winston Dugan) thanked his hearers sincerely for the very kind welcome they had given him. He said that he was very interested in the man on the land, and particularly the man who was striving hard under very adverse conditions outback. This was the man he wanted to see—the pioneer who was the great descendant

of those men who came out here in the early days, and made Australia, and particularly South Australia, what she was to-day. So far he had visited only a few country districts, but in each of them he was tremendously impressed not only with the loyalty which everyone expressed towards His Majesty the King and the British Empire, but also with the warm welcome and the hearty way in which everyone shook him by the hand.

It was the man on the land who was going to make and improve this great State, and at the Congress there were representatives of men and women who were engaged in agriculture banded together to learn something to increase their knowledge. Science had come to their aid in many respects, and experts who were carrying out investigations were in a position to teach the farmer how to improve the conditions under which he lived. He did not include himself as an agriculturist, but he was very interested and anxious to learn, and they were present at the Congress to learn how to overcome their difficulties and trials, and to improve their conditions in order to go further towards prosperity. In the short time he had been in South Australia he had learnt a good deal about the conditions under which the people on the land lived, and he realised what those difficulties were, and he also knew how well those difficulties were being surmounted.

His Excellency continued that he fully realised the great work that was being carried out by the Agricultural Bureau, and the important investigations which were being made in the producers' interests; and he asked delegates to consider very seriously the question as to whether more people should not join the Bureau and take advantage of the knowledge and information which was there to improve the conditions on the land. In some cases science had converted what might have appeared to be a barren desert into a valuable soil, and there was no reason why science should not go further, and even improve the conditions which were brought about by drought. He trusted that the Congress would teach the delegates a good deal, and give some help in the trials and difficulties, as well as the problems in which they were engaged.

THE MINISTER'S ADDRESS.

The Hon. A. P. Blesing, M.L.C. (Minister of Agriculture) congratulated His Excellency, on behalf of the Agricultural Bureau, on his assumption of office, and expressed pleasure to see that, like his predecessors, he was taking an early opportunity to associate himself with our rural interests. He assured His Excellency of the appreciation and support of all the men on the land. The Minister congratulated members of the Agricultural Bureau on their 45th Congress, and hoped that it would prove as successful as the best Congresses of the past. Forty-five years of continuous work was a long span for an organisation of this kind; but since the Agricultural Bureau and its Branches extended from Warcowie in the north to Allandale in the south, and from Fowler's Bay in the west to Pinnaroo in the east, the system was entrenched in the affections of the people, and as such would go on for ever, or until such time as high tariffs succeeded in driving the last South Australian farmer off the land. He expressed his own appreciation of the Bureau as an old member of long standing.

Referring to seasonal prospects, Mr. Blesing said the autumn and winter rains were deplorably low, and by the end of July there was no feed and few crops above ground. August proved wonderfully good throughout the State, and for the time being saved the situation. Although feed continued scanty, crops began to make progress, and were supported by early September rains. With a favourable October and early November, the season might finish satisfactorily.

As Minister, he had been concerned with several important Agricultural Bills. Unfortunately, two were rejected in the Upper House, namely, The Sale of Fruit Act Amendment Act, 1934, and The Agricultural Seeds Act, 1934. That was

regrettable, because it was essential that farmers should be protected in the purchases of seed which they were compelled to make from time to time. It was not only the loss of money that was of importance, but chiefly perhaps the waste of time. The Fruit Grading Act, the Tobacco Act, the Pest Destroyers Act, Dairy Acts, and the Margarine Act were still being considered. It was anticipated that they would be passed, and prove useful to the rural community.

Changes in the Department of Agriculture.

Mr. George Quinn, who for 47 years had served the State in various capacities, was due to retire last February. It was realised, however, that for many years data of considerable importance had been accumulating at the Blackwood Orchard, which since its inception had been controlled by Mr. Quinn. All these data, however, and the costs of collecting them would have been wasted unless early steps were taken to analyse them and present the conclusions to be derived therefrom in a form available to fruitgrowers and gardeners generally. Accordingly, on Mr. Quinn's retirement the Government decided to retain his services for this purpose, and it was hoped that all those concerned would soon be in a position to benefit from work done at Blackwood for the past 26 years.

Mr. C. H. Beaumont, Horticultural Instructor, had recently retired. The Minister thanked Mr. Beaumont for the 21 years of work well and faithfully carried out.

Drawing attention to the growing dependence of rural undertakings upon exports, Mr. Blesing said the countryside could not expand and develop unless successful export outlets were found for surplus produce. Wheat and wool they had always been able to export, although none too successfully of late. The State was now exporting butter, cheese, dried fruits, apples, pears, oranges, mutton, lamb, pork, eggs, &c.—almost everything they were able to grow. He stressed the importance for all export products of uniformity of type, quality, and continuity of supplies, and deprecated the export of second-hand and third-class goods. Australia, owing to her great distance from the main markets of the world, must build herself up a name for excellence in everything she brought to market. It was true that inferior meat, poor butter and fruit, &c., could find a market abroad at a price; but the mere offer for sale of low-class goods would eventually stamp the country they came from as a country of inferior goods. Inferior prices would be the result, and a bad name which it would take years to live down. If inferior goods could not be utilised at home they had better be destroyed than sent abroad.

The Minister hoped that the findings of the Federal Royal Commission on Wheat would be such as to give relief to wheat farmers on a rationally conceived and firm basis until such time as world recovery was complete and prices normal.

He trusted that the deliberations of the Congress would be successful, and assured members that their requests would receive the earnest and sympathetic consideration of the Government.

CHAIRMAN'S REPORT.

The following report was read by the Chairman of the Advisory Board of of Agriculture (Mr. A. J. Cooke):—

"For the second occasion it has fallen to my privilege and pleasure to preside over a Congress of the Agricultural Bureau. This privilege is extended to few and consequently it is the more highly appreciated, particularly when it is remembered that delegates who attend such gatherings are representatives of producers in important districts of the agricultural areas of the State.

Right from its inception—46 years ago—the Agricultural Bureau has had a marked influence on the agricultural practices of South Australia and the organisation may be congratulated on the fact that it has never lost faith in itself,

that it has continued successfully as an educational institution and that it has developed that spirit of mutual help and co-operation which means so much in fostering the well-being of the farming community.

Remarkable progress has been made within the past 10 years, during which period over 100 branches have been added to the list, with a net increase of 1,200 members. Even during recent years there has been an increase in the number of branches which on June 30th last stood at 336. The peak year of membership was in 1931 when the members numbered some 8,500. While the years of depression persisted there may have been some excuse for a drop of 500 to 600, but it is most interesting to note that during the recent months of August and September no fewer than 350 new members have been added to our rolls. This appears to show a stimulated interest in some districts and I sincerely hope that this example will be followed by other parts of the State.

Continuing the practice of previous years, I desire to make a short reference to the work of the Board in its relation to the Branches which it controls. Numerous items have been submitted for consideration and the Board has endeavoured to deal with them in an honest effort to bring about an improvement in the agricultural practices in various sections of primary production.

Let me mention that during the year Mr. P. H. Jones—a past chairman—resigned his seat on the Board on account of other duties, and we are pleased to place on record our high appreciation of his services. The Minister has appointed Mr. A. J. A. Koch, of Lameroo, in his place. Mr. Koch is well known as a public spirited farmer, and one who has a wide practical knowledge of South Australian Agriculture. He is a life member of the Bureau, and we look forward to his help and advice, particularly in regard to the agricultural conditions applying to the mallee districts of the State. Two members of the Board—Messrs. R. H. Martin and S. Shepherd—are at present travelling aboard and Mr. Shepherd was granted a commission to inquire into agricultural and pastoral conditions in other parts of the world. Our association with these gentlemen assures us that the State will benefit by the store of information which they will bring back with them.

Besides the control of the Agricultural Bureau, the Board acts in an advisory capacity to the Honourable the Minister and realises its responsibility when approaching the Minister on matters which it considers are of importance to the welfare of farmers. It is unfortunate, however, that although we have the full sympathy of the Minister, there has not been that improvement in the State's finances which would enable him to shower upon us all of the things which he may be called upon by branches to bestow. We have, however, appreciated his efforts in securing for us the continuance of the Annual Congress this year.

Also, the grant of £100 for the purpose of providing prizes in wheat crop competitions following a similar donation by the South Australian Farmers' Co-operative Union last year, will, it is hoped, further stimulate this class of educational activity in the wheat-growing areas of the State.

Further, the provision on this year's Estimates for a veterinary scholarship, originally suggested by the Principal of the Roseworthy College and recommended by the Board, should appeal to all members of the farming community.

Fruit growers, too, will be pleased to learn that there has been a compliance with their request for the recording of the experimental work and results at Blackwood Experimental Orchard. Mr. Quinn's services have been retained for the purpose and we look forward to the compilation of data which will be most useful to horticulturists here and abroad.

The appointment of Mr. A. G. Strickland as Deputy Chief Horticultural Instructor will, I am sure, meet with the approbation of branches specially interested in fruitgrowing. His attendance at branch meetings and conferences will be most welcome and I trust that fruitgrowers will not fail to make full use of his services.

Acting on the request of branches a series of articles, with coloured illustrations, on the "Important Weeds of South Australia" is now appearing in the *Journal*, under the authorship of Mr. G. H. Clarke, of Roseworthy College.

The reclaimed swamp areas along the River Murray are receiving Departmental attention and the Board appreciates the action of the Minister in making available the services of Mr. R. Hill in an advisory capacity to the settlers there.

There appears to be a general desire for the appointment of veterinary officers for country districts and representations have been made by the Board to the Government accordingly. This matter will be dealt with at the Free Parliament session.

During the present year special representations were made to the School of Mines for the services of wool instructors and many branches have been visited. It was impossible for the staff to give all of the branches immediate attention and the result has been that several requests will be carried forward to next year. The question of the appointment of an officer to the Department, which had been held in abeyance, has been reviewed by the Board in accordance with the Congress resolution, and a subsequent resolution at the Caliph Conference. A statement of the position has been submitted to the Minister for his consideration.

During the year a Royal Commission on the important question of the Wheat Industry took evidence in South Australia. The co-operation of the Agricultural Bureau was sought and we were thus able to place before the Commission, either by direct evidence of members or by collective questionaires, the opinions expressed from time to time on expediencies, either permanent or temporary, which might give farmers the assistance which they have desired in order to place the wheat industry on a better footing. We were represented by two members—Messrs. F. Coleman and A. L. McEwin—and the Board was able accordingly to stress the necessity for revision of tariffs as requested at Congress and Conferences. The case for a home consumption price for wheat was also placed before the Commission and it is noteworthy that in its First Report, the Commission recommends that the principle of a home consumption price should be applied to the wheat industry. No recommendation appears to have been made so far by the Commission in relation to a reduction in tariffs.

During the year we have seen a reduction in the price of kerosene, a matter which came before Congress, but we have yet to hear of favourable consideration in the matter of a reduction in the duty on this article as well as on petrol.

The Board has given its support to requests that legislation be passed to give effect to many of the recommendations of the Report of the Royal Commission on Dairy Industry Prices.

Representations were made to maunfacturers for a reduction in the price of superphosphate. Attention was drawn to the reduced price in the South-East, a condition which the manufacturers claimed was entirely due to a price war with Victorian companies. The "war" appears now to have extended over a wider front than the South-East and until the price is reduced for supplies to other districts the position will no doubt remain unsatisfactory to farmers generally.

A request was sent to the Federal Government asking for a renewal of the subsidy to users of manures to crops other than wheat crops and we have recently been informed that similar concessions to those of last year would apply this year.

The Royal Agricultural Society provided in this year's Prize Schedule, a condition that non-subscribers might enter in the agricultural produce section on the payment of a small fee. The question of extra financial assistance for the staging of Bureau Exhibits will be taken up with the Society after the completion of this year's Show.

Bulk Handling of Wheat was referred to the Government, but we have been informed that no action is to be taken for the present.

It was announced by the Chief Inspector of Stock that the complete isolation of contacts is one of the routine measures for the control of pleuro-pneumonia in stock, and that if in the opinion of an Inspector, a double fence is necessary to obtain effective isolation of paddocks, instructions are issued to the owner accordingly.

The Board has given its support to the Congress resolution asking for the introduction of legislation to provide for a Cattle Compensation Fund on the lines similar to that in Victoria, and we are in agreement with the opinion expressed at Congress and Conferences that the dehorning of bulls should be compulsory. These matters have already been submitted to the Government and it will be noted that the subject of dehorning will be discussed again at this year's Congress.

The prevention of bush fires has had the attention of the Board during the year, and it will be noted that the 1933 Act provides that inquests shall be held on certain requests being made. This matter was brought up at the 1933 Congress and further consideration is being given by the Board to other proposals from branches.

In reply to a Congress resolution, the Railways Commissioner pointed out that the difficulties experienced on Eyre's Peninsula in regard to rail freights are brought about mainly by reason of the long hauls from Port Lincoln to the inland towns, and that the scale of charges is the same as that applicable to the mainland.

The question of destruction of rabbits has had the consideration of the Government, and branches were informed that provision was made on the Estimates for the purpose. Portion of the amount would be used for the purchase of poison. No action has ever been taken to destroy rabbits on Crown lands generally in view of the large areas involved.

In connection with the request of Congress asking that details of interest should be shown on forms under the Farmers' Relief Act, an explanation was given to Branches indicating how the information could be obtained from the forms supplied.

No action was taken with reference to the request for the abolition of the system of selling wheat within a stated time under the provisions of the Farmers' Relief Act, as it was considered that this was a business matter outside of the scope of the Board.

The Board did not feel that it could push the request of Congress that more representatives of farmers should be appointed on the Farm Relief Board or on the Farmers' Assistance Board, as the Government could not be expected to grant representation of any one section of interested parties to a greater extent than other sections.

In accordance with last year's Congress resolution, the Bureau household subscription of 2s. per annum commenced in August. Although Branches have been given up to December 1 for the final revision of our rolls, it is very gratifying to be able to state that during August and September the returns of 50 per cent. of the Branches have been supplied. This work necessitated further tasks on Branch Secretaries, whose general efforts on behalf of their Branches are highly appreciated by the Board.

Although it is fully recognised that the number of Women's Branches has steadily increased, the Board has not felt justified in making a recommendation for the appointment of an organiser at present.

It will be noticed that the Agenda Committee has given special prominence to the poultry industry. No farm can afford to neglect this class of production, and a special paper on the subject will be read by Mr. C. F. Anderson (Poultry Export) to a combined meeting of the Men's and Women's Branches. After the completion of this paper a visit will be made by women members to Mr. Gameau's commercial poultry plant in order to view up-to-date methods of rearing and management.

Throughout the year there has been a continuance of the cordial relationship between the officers of the Department of Agriculture and the Board, together with the Branches of the Bureau. The Board has a very high opinion of these officers, and judging by the steady flow of requests for their services, is convinced that their work is appreciated by members of Branches. A close contact between the Departmental Officers and the farmer is essential for the improvement of our agriculture, and this is rendered possible through the medium of the Agricultural Bureau.

The meetings which were convened by Branches to hear the Trades Commissioner (Mr. C. F. G. McCann) may be quoted as instances to prove that we have the organisation always ready to call together the farmers of almost any district in the State for the purpose of imparting the most recent information on subjects in which the farming community is particularly interested.

Whilst I am aware that the advice and opinions of officers are sought by Branches generally, I may be excused for stressing the importance of this feature of agricultural education which the Department of Agriculture offers to the producer. I have had the privilege of attending Bureau District Conferences, and have been impressed with the eagerness with which members have listened to addresses and replies to questions by officers. This shows that opportunities exist for the acquisition of sound agricultural knowledge ; it is then only necessary for the farmer to take advantage of these opportunities by his attendance at the meetings which are convened for his benefit.

There has been a marked improvement in the work of the Women's Branches, which now number 45. At to-night's meeting there may be representatives of Men's Branches in districts where Women's Branches have not yet been formed. To these I would suggest that if their Branches are in any way lapsing into inactivity they should take early steps to have Women's Branches established, as we find that wherever Women's Branches exist the men show greater interest in the affairs of their own Branches. The Women's Branches have also been of great assistance in arranging Conferences, and very often the success of such gatherings has been largely due to their efforts. We have again been fortunate in having the services of Miss Campbell, of the Education Department, at Conferences and at many of the Branch meetings. The fact that her attendance at meetings is in constant demand is ample evidence of the popularity of her addresses and of the high opinion which Branches have formed of her work. A special agenda has been prepared for the Congress of Women's Branches, and I trust that they will derive the full benefit of the information which will be made available to them.

Concluding, I desire to express the pleasure of the Board at seeing so many delegates here to-night, and to convey to you our sincerest appreciation of the work you are doing for the well-being of the Agricultural Bureau of South Australia."

TUESDAY, OCTOBER 9th.

Morning Session.

The following papers were read:—"Generalities Concerning Farm Poultry," Mr. C. F. Anderson (Government Poultry Expert); "The Quality of Dairy Produce and Its Effect on Marketing Conditions," Mr. H. B. Barlow, H.D.A. (Chief Dairy Instructor); and "Fat Lambs," Mr. T. R. Secker (Tumby Bay).

These papers will be printed as separate articles.

Afternoon Session.

Mr. A. H. Robin, B.V.Sc. (Stock and Brands Department), read a paper, "Some Preventable Diseases of Pigs: Minerals for Pigs," and Mr. R. C. Scott, R.D.A. (Superintendent Experimental Work) spoke on "Pasture Species for the Non-Irrigated Grasslands of South Australia."

These papers will be printed as separate articles.

Horticultural Session.

The following addresses were delivered:—"Recent Investigations on the Apple Thrips and Green Peach Aphis," Dr. J. Davidson (Waite Research Institute; "From Seed to Fruit," Mr. H. N. Wicks (Member Advisory Board of Agriculture); and "Orderly Marketing," Mr. J. B. Murdoch (Member Advisory Board of Agriculture).

Evening Session.

Professor A. J. Perkins (Director of Agriculture) read a paper, "Some Parting Reflexions on Wheat Growing in South Australia," which will be published in the Journal as a separate article.

WEDNESDAY, OCTOBER 9th.

Morning Session.

FREE PARLIAMENT.

Mr. A. J. Cooke presided, and the following resolutions were carried:—

"That this Congress supports the Advisory Board of Agriculture in its recommendation to have veterinary surgeons appointed in country districts of the State."

"That Govenment instructors should judge crops not at the direct expense of farmers."

"That effective measures be taken to discourage the growing of Gallipoli wheat or any other of low-milling quality."

"That if unable to lower the telephone charges the time limit for people living more than 25 miles from the G.P.O. be extended."

"That the 1934-35 wheat bounty be paid on an average basis for yields of 10bush. and lower, and that on yields of over 10bush. payments be made at per bushel."

"That all discounts obtained on settlers' behalf be credited to the settler instead of the Assistance Board."

"In view of the excessive charges farmers have to pay in certain directions, we consider a lump sum should be paid quarterly for sustenance and clothing to be spent at settlers' discretion."

"That the Government be asked to make all the money provided under the Advances to Settlers Act for fencing available to farmers."

"That the Government be asked to review the water situation in districts where permanent wells or springs have not been found, and which are not likely to be reticulated for some time from some reliable reservoir."

"That the Government be asked to supply settlers with galvanized iron and cement free of tariff charges for the purpose of making artificial catchments for water."

"That no points be deducted by judges at the Royal and Agricultural Shows for dehorned bulls, and that the Government be asked to introduce a law making it compulsory for all bulls to be dehorned."

"That only Alsatian dogs registered in a stud book be allowed in the country."

"That the Commissioner of Railways be urged to run trains and buses where profitable to suit the requirements of the people instead of forcing them to use other means of transport."

"That freights on all merchandise and particularly stumps be reduced on railways at least 25 per cent."

"That Eyre's Peninsula be granted free transport for all merchandise and livestock to and from Adelaide (free transport to mean free from control of the Transport Control Board)."

"That all revenue raised by the Government for motor taxation be used for construction and maintenance of roads, and that by employing the unemployed on road construction a very great saving could be made in the unemployed relief expenditure."

"That Congress support the early introduction of bulk handling of wheat."

"That bags are not up to standard size, and this Congress strongly recommends that this matter be dealt with."

"That the dockage on wheat at country sidings in the Kimba district of 1¼d. below f.a.q. is considered very unfair."

"That the Monday evening session instead of closing at 9 o'clock or thereabouts be extended for at least one hour, which shall include a paper or an address."

"That the Government bring in a Bill to provide for the registration of veterinary surgeons."

RESOLUTIONS LOST.

"That the Government be asked to subsidise the purchase of good rams with a view to improving farm flocks."

RESOLUTION LAPSED.

"That Congress be held Monday night, Tuesday morning, Tuesday night, Wednesday morning, and Wednesday night to give delegates the opportunity to attend the show in the afternoons."

Evening Session.

Dr. A. R. Callaghan, Principal of the Roseworthy Agricultural College, gave an address, illustrated with lantern slides, "The Conservation of Fodder Under South Australian Conditions," a digest of which will appear in a subsequent issue of the *Journal*.

On Thursday morning delegates visited the Waite Research Institute.

THE USE OF CHEMICALLY TREATED CORRUGATED BANDS AS A SUPPLEMENTARY CONTROL FOR CODLIN MOTH.

[By R. FOWLER, Manager Blackwood Experiment Orchard.]

During recent years, owing to the added costs of looking after the plain bandages and the fact that with the introduction of arsenate of lead as a spray for codlin moth, a better measure of control has been attained, the practice of bandaging has fallen into disuse. In some districts where, owing to climatic conditions, it is easier to control the codlin moth by efficient spraying methods than in others, it may be uneconomical to apply bandages either chemical or plain, but there are not many districts where a determined effort is not necessary to reduce the moth population if serious loss is not to result. With the least relaxation of effort, or with no appreciable relaxation at all, there is sometimes a big increase of codlin moths in some seasons, and it is only by using all the measures known to us that we can get them in control again.

In more or less neglected orchards, where, through stress of circumstances, it is not possible to give proper attention to spraying, the chemical bandage offers a means of control that requires the minimum of effort on the part of the grower. I foresee the time when the Department of Agriculture will make the use of chemical bandages compulsory, or at the discretion of the Orchard Inspector. They would be more effective than the present methods used in many small gardens.

The idea of using chemically treated bands originated in America. In 1930 Siegler and Munger, of the Bureau of Entomology, first issued a report concerning their use, and in 1931 further experiments were made by other scientists, to determine the most effective width of band and the exact concentration of toxic material to use to get the best results. Since then further investigations have resulted in a very effective, though somewhat expensive, band being placed on the market. As the demand for these bands increases costs will no doubt be reduced.

These bands were first used in the State Experiment Orchard during the 1932-33 season, 100ft. of material being secured for the purpose. This proved sufficient to bandage 50 average sized trees. Counts of codlin larvae were made throughout the season, and, finally, the bandages were removed in June and further counts made, which revealed that 764 grubs were caught in the chemical bandages and 869 in bag bandages applied to the same trees, but above the chemical bandage. The results of this experiment indicated that it was desirable that further tests should be made, and last season (1933-34) a full roll of 200ft. of chemical bandage was used. This proved sufficient to bandage 96 average sized trees.

These bands were put out on December 26th, when the first grubs were beginning to appear in the ordinary bandages. It is well known to every fruitgrower that the moths from the over-wintering larvae emerge about blossom time, *i.e.*, towards the end of October. These moths lay eggs, the young grubs when hatched enter the fruit, take about three weeks or more to develop, and then, when fully grown, leave the fruit and seek a dark, protected place in which to spin their cocoons.

TIME OF APPLICATION.

Generally it will be found that the first mature grubs will be on the move about the middle of December, and it will be quite early enough if the bands are put on about that time. It has to be remembered that the toxic effect of the bands is likely to diminish on exposure to the weather, particularly if heavy or continuous rain occurs, so that it is not advisable to put them out until there

is some indication that there are grubs leaving the fruit. At the same time it is important not to delay too long, as it is most desirable that as many as possible of the first-brood grubs should be caught. The more first-brood grubs that are caught the less will be the damage caused by the second brood. It is generally assumed that most of the grubs on leaving the fruit, if the fruit has not already fallen, spin a web and thus reach the ground, and then look for shelter beneath the loose bark of the tree trunk or larger limbs, though they will sometimes find suitable quarters in debris of various kinds, such as stakes, props, &c.

In our experiment in 1932-33 we placed an ordinary bag bandage above the chemical band, and on the average caught a few more in this bandage than in the chemical band, so that apparently a number of grubs move down as well as up the tree. It is necessary, before applying the bands, to scrape off thoroughly all rough bark on the trunk of the tree, and in view of the fact just mentioned that grubs appear to descend as well as ascend, it would also be advisable to remove as many hiding places as possible above the trunk, in order to make the band the only harbour.

The bands were applied on December 26th and left undisturbed till May 31st. As the bands are made of corrugated cardboard, which is rather easily torn, some care is necessary when adjusting the band to the tree. A special clip is provided for fixing the band, but it may sometimes be advisable to use more than one clip on each bandage to ensure that in the uneven portions of the trunk the band fits fairly closely, otherwise it might be possible for grubs to hibernate without coming in very close contact with the chemical matter contained in the bands. These grubs might escape destruction. A few empty pupae cases have been observed, indicating that a few grubs have not been killed, but this small percentage of escaped insects is not sufficient to condemn the bands as ineffective. If the bands do not fit snugly, or if the portion of the trees beneath the bands has not been well scraped, it is possible a few grubs may spin their cocoons without coming in actual contact with the chemical and may not be killed, but the percentage that will escape in this way will be small if ordinary care is used when fixing the bands.

The bands seem to become less effective towards the end of the season, the killing action evidently becoming slower, and it might be desirable to leave them on until well into June, so that any live, but very sick worms, may be killed. This may not always be possible. We had to remove them at the State Orchard at the end of May, because magpies were tearing them off, presumably having found live grubs to eat.

A careful count of the grubs trapped by the chemical bands was made on removal. To do this great care was exercised when removing the bands, as many grubs were found between the bands and the tree. A count was made of the grubs in this position. The bands were then torn apart and a count made of the number that had made or attempted to spin cocoons in the inner channels of the corrugated cardboard. In most cases the grubs did not live long enough to spin a cocoon, but when they did, they were invariably alive within it, though in most cases very sick. That they had been affected by the chemical was indicated by their appearance, as, instead of showing the natural creamy-white colour of the codlin grub, they had changed to a reddish-brown, usually with very dark lines showing right along the back. It would seem probable that most of these affected grubs would die before the following spring, or that their future development would be seriously interfered with. That this is so seems to be indicated by the fact that of 138 similarly affected grubs placed in a breeding cage at the Waite Institute by Dr. Davidson from the 1932-33 catch only 18 emerged as moths in the spring of 1933.

The 96 trees on which the chemical bands were used during the past season were in the variety plot and carried mostly heavy crops. Early, mid-season, and

late ripening types were represented. They were sprayed four times with arsenate of lead—3lbs. of powder in 100galls. of water. The percentage of codlin fruit at picking time did not seem excessive, but 6,165 grubs were caught in the chemical bands—an average of 64 per bandage. Of these approximately 2,500 favoured a position between the band and the trunk of the tree, and 3,600 elected to hibernate in the inner channels of the corrugated bands. Of the total number of grubs caught approximately 1,600 were alive, but most of them had been more or less affected by the chemical in the bands, and would probably have died later. There was, however, a certain number that had evidently entered the bands very late in the season and did not appear at all affected, proving that at this period the bandage has little toxic property left, and that it should not be allowed to remain till it rots off the tree, but should be carefully removed at the end of May, or the beginning of June, and destroyed. An easy method is by burning, as the material is fairly inflammable.

In order to gain some information relative to the habits of the codlin larvae when seeking to hibernate and to ascertain if the chemicals in the bands acted as a repellent in any way, on the assumption that the grubs would, by instinct, avoid a situation that meant death to them, ordinary bag bandages were placed a few inches above and below the chemical bands on 10 trees. Weekly counts were made of the grubs in the ordinary bandages and the chemical bands were examined at the end of the season. A total of 767 grubs were trapped on these trees, 209 in the top bandages, 392 in the chemical bands, and 166 in the lower bandages. These figures are somewhat instructive and contrary to what one might expect. Evidently the codlin grub, when seeking to hibernate, does not accept the first comfortable position offering, but has a good look round before settling down, and the fact that 392 grubs out of 767 apparently passed over the good bag bandage and proceeded to spin a cocoon in the chemical band indicates clearly that either the codlin grub has no sense of danger or that there is nothing about the chemicals used in the bands to repel them. It is also surprising to find more grubs in the top bag bandage than in the lower bag bandage.

It is hard to say what proportion of the grubs caught in the bag bandages would have gone to the chemical bands if the bag bandage had not been there, but it is safe to assume from this data, and that collected in the previous season, that fully 50 per cent. of the grubs moving about the trees will be caught in the chemical bands, and that they are, therefore, 50 per cent. efficient. In an orchard heavily infested with codlin this would represent a considerable number of grubs. The value of the automatic band is cumulative, and they should materially assist in reducing the codlin moth population in the orchard if used in successive seasons. Particularly should this be the case where dependence is placed on spraying alone and no bandages are used owing to the added cost of examining them. The chemical bands, as previously stated, offer an easy way of killing thousands of grubs in otherwise neglected orchards and back yard gardens.

The chemical bands will not do away with the necessity for spraying, as apparently 50 per cent. of the grubs do not enter the bandages, but the sprays will have less work to do and the final result should be much cleaner fruit.

It is generally recommended that the chemical bands should not be applied to young trees with smooth bark, as injury may result, but they are quite safe on bearing trees that have developed a tough, if not rough bark. We have used them for two seasons on trees 23 years old, many of which have quite smooth bark, but beyond a slight discolouration where the band has been, the injury, if any, is too slight to affect the health of the tree.

There might be some advantage also in placing rolls of chemically treated bands in the packing and fruit house during the season, as the codlin appears to have a gregarious instinct and likes to collect in numbers in one place.

It was noted in 1932-33 that bands taken from trees affected by Woolly Aphis contained thousands of dead aphides, evidently caught while migrating to the roots for the winter. This was not so noticeable during the past season, as very few trees showed any sign of Woolly Aphis, due to the good work done by the *Aphelinus mali* parasite.

At the present time the high price of the bands prohibits their very extensive use, but it appears possible that these costs can be materially reduced.

The band consists of a strip of corrugated paper thoroughly coated with a toxic mixture of beta naphthol and oil. Beta naphthol may be obtained from manufacturers and dealers in chemicals and the engine oil from any oil company.

Comparative tests in America have proved that a 2in. band affords sufficient cocooning space to take care of any normal infestation. A wider band, therefore, would only add to the costs unnecessarily.

Formula—

Beta naphthol	1lb.
Lubricating oil	1½ pints

Cost.—The cost of materials will depend on the quantity used and where purchased. In Victoria they are quoted as follows:—

Bands—200ft. roll strawboard	2s. 6d. each; 10 rolls	1s. 10d.
Beta naphthol	1s. 9d. pound	
Engine oil (4gall. tins)	3s. 3d. gallon	
Thermometer (glass)	6s. 6d.	
Leather gloves	2s. 6d.	

The estimated cost for 3in. bands being less than 1d. per tree.

In America the estimated cost for a 2in. band is 1 cent. per linear foot, or 1 dollar = 4s. 2d. per 100 ft.

METHOD OF PREPARATION.

Mix the beta naphthol and oil into a suitable container and heat until all the beta naphthol has gone into solution. Continue heating until a temperature of 265° to 270° Fahr. is reached. Maintain the temperature within this range throughout the treating process.

Care should be taken as beta naphthol boils between 280° and 286° Fahr. Both beta naphthol and oil are very inflammable, but not explosive. If the temperature of the mixture is too high the band will not have a sufficiently heavy coating. On the other hand, if the temperature is too low there is a greater tendency for the corrugated tubes to become clogged at the openings. The bands should not be prepared indoors if an open fire is used as a source of heat. The beta naphthol crystals, which resublime in the air, are more or less irritating to the eyes and skin, and to the mucous lining of the nose, and the fumes should be avoided as much as possible. Much handling of the mixture will often cause a tingling or numbness of the fingers, but this condition passes away without any serious consequences.

The rolls of corrugated strawboard should be immersed in the solution when at the right temperature for approximately one second, and the dipping process should be repeated, thus securing the right weight of chemical coating. The weight recommended is 1oz. to each linear foot of 2in. band.

A complete double dipped roll of 125ft. would, therefore, weigh about 10½lbs. Rainfall and temperature are factors in determining the proper weight of coating. Since the loss of toxic chemicals resulting from these factors cannot be predicted in advance, it is better to be on the safe side than to use a band which is inadequately coated.

The directions given for preparing the bands are those recommended by E. H. Siegler and F. Munger, of the Bureau of Entomology, U.S.A. These gentlemen have done a considerable amount of experimental work with chemical bands.

STATE OF SOUTH AUSTRALIA.

VARIETIES OF WHEAT SOWN, SEASON 1933-34.

[A. W. BOWDEN, Acting Government Statist.]

1. The Acting Government Statist reports that 186 (183) varieties of wheat were reported as sown for the wheat crop of the season 1933-34. The total acreage sown for grain, hay, and fodder was 4,074,417 (4,274,096), of which the varieties were not specified for 102,941 (139,560) acres.

2. Particulars of the 16 most popular varieties are given at foot hereof. Nabawa has occupied first place during each of the last three seasons, the proportion to the total being a little higher each season. This season Ranee has risen from fourth position to second, displacing Gluyas, which had held first place prior to 1931-32. Gallipoli again holds third position, with an increased proportion to the total. Sword is one of the newer varieties which increased from 139 acres in 1930-31 to 23,047 in 1932-33 (twenty-fourth on list), and this season rose to eighth position, and Ghurka has risen from twenth-eighth to sixteenth. The two leading varieties accounted for one-third of the total area sown, while the leading four accounted for more than one-half.

3. *The leading varieties favoured in each of the Divisions, and their percentages to the total were*:—Central—Nabawa, 24; Ford, 10; Ranee, 9; Waratah, 8; Sword, 7; Gallipoli, 6. Lower North—Nabawa, 20; Ranee, 12; Ford, 10; Gallipoli, 9; Waratah, 8; Gluyas, 5. Upper North—Ranee, 34; Nabawa, 20; Federation, 11; Gallipoli, 6; Waratah, 4. CODLIN MOTH CONTROL.

RESULTS OF EXPERIMENTS AT BLACKWOOD, 1933-34.

[R. FOWLER, Manager Blackwood Orchard.]

The 1933-34 season was an "on" year so far as the apple crop at this station is concerned, and as is usual under such circumstances, the control of the Codlin Moth appeared to be more efficient than is possible in the "off" years. A long, dry, and hot summer was experienced which covered practically the whole growing period of the fruit and extended well into harvesting time, with the result that there was much undersized fruit, and picking was unduly delayed. To enable the fruit to develop into the export grades, much of it had to remain on the trees weeks longer than would have been the case under normal conditions. This meant that in the experimental plots the fruit was exposed to Codlin attack for various periods as fruit on some trees developed more rapidly than on others. As an illustration, Cleopatra were harvested from the beginning of March to the end of April—a period of eight weeks—and many Codlin Moths were on the wing up to the middle of March. The weather conditions generally throughout the summer might be considered as favourable for the development of Codlin Moth.

The experiments this season were designed with the idea of again testing the value of summer oil sprays—

(1) In combination with arsenate of lead, both in standard and reduced quantities.

(2) Used alone after two early arsenate of lead sprays.

(3) Used alternately with arsenate of lead sprays.

(4) Used in combination with nicotine sulphate as a final spray.

Two important factors have to be kept in mind when preparing spray schedules. The cost of the sprays and their influence on the amount of arsenical residue. To be of economical value, the results must be satisfactory from both these points of view.

In addition to spraying tests, further studies were made with—

(1) Lures and bait traps, both as a means of reducing the moth population in the orchard, and as an indication of the emergence of moths to determine the best times at which to apply the sprays.

(2) Bandages, both chemical and the ordinary bag bandages for trapping grubs after they have left the fruit.

BAIT TRAP, OR LURE EXPERIMENTS.

Experiments in this direction have been carried out at this Experiment Station since 1925; and have been fully discussed in previous reports issued by the Agricultural Department. In the early experiments several different liquids were tried for attracting the moths to the traps, and after numerous trials it was found that molasses at a dilution of 1 in 10 gave the best results. This lure was found, after many careful records had been made, to attract more moths than either vinegar or fermented apple juice, and at the same time was not so destructive to other beneficial insects, such as Ladybirds and Lacewing Flies. Consequently, molasses solution has been used in our experiments for some seasons.

In all, 49 traps were used in different parts of the orchard, and regular weekly counts of the moths trapped and at intervals sex determinations were made. The first moths were caught in a trap near the fruit sheds on October 23rd, and in the

experimental traps the first count was made on October 30th. The results of the trapping tests will be found in Table I.

A study of the figures shows that a considerable number of moths can be caught by this means, each trap in the experiment averaging 41.4 moths for the season. From an examination of 1,146 moths it would seem that in the early part of the season there are slightly more females than males, 54.5 per cent. to 45.5 per cent., and that the proportion of females to males increases towards the end of the season, 67.3 per cent. to 32.7 per cent. No dissection of females was made, as previous determinations in this direction have proved that most of the females, when caught, are either gravid or in a fit condition for egg-laying, it seems safe to assume that if lures were used systematically throughout the orchard the moth population could be considerably reduced, and a cleaner crop result; but efforts to prove this in previous experiments by comparing results from trapped and untrapped portions of the orchard were not successful.

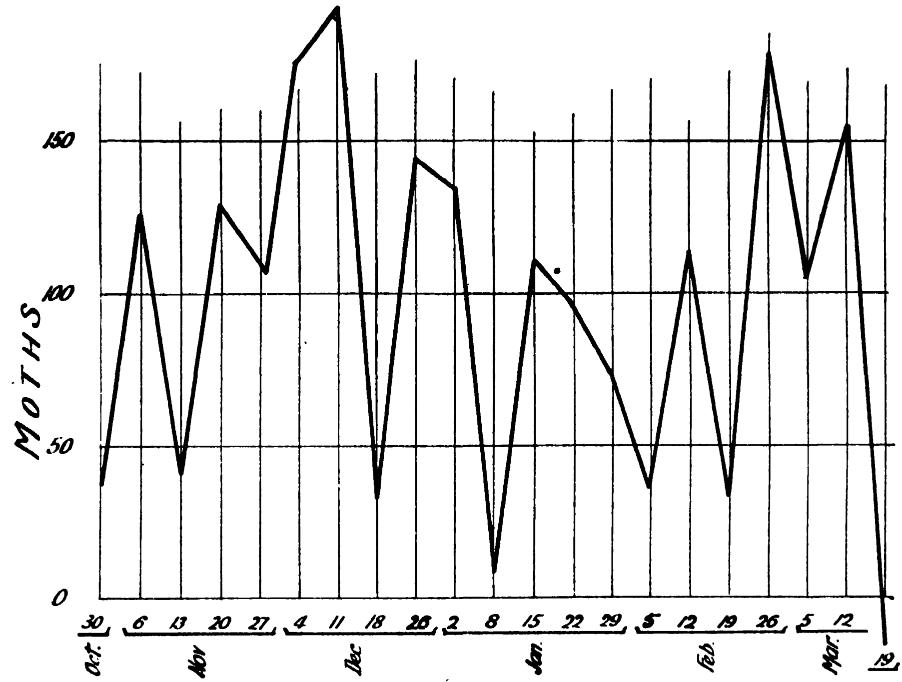
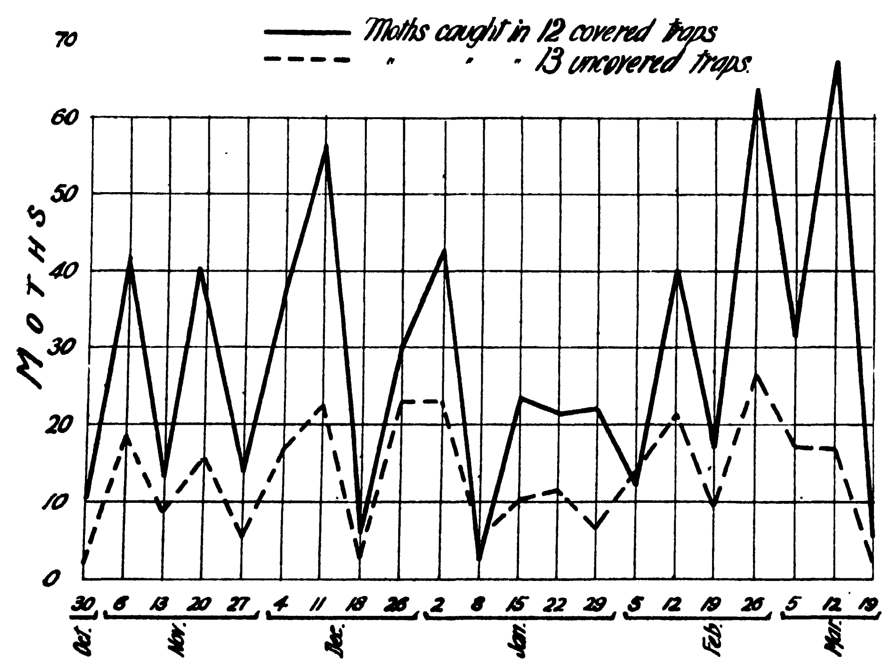
19.3.34	9	4	5	9	
Total ..	2,031	522	624	1,146	

Quite apart from their value in reducing the moth population, the lures do indicate when the Codlin Moths emerge in the greatest numbers and are most active. Consequently sprayings can be timed so that they should give the best results. This was pointed out in the first report on Codlin Moth experiments from this station, issued in 1926, and graphically illustrated on page 6 of Bulletin 201, issued by our Department of Agriculture. It was noticed when plotting this graph that when sprays were applied on a time schedule, as had always been the practice, that they did not always coincide with the periods of maximum emergence of moths, and in this particular season our third and fourth sprays were applied 6 or 7 days too late to expect maximum results.

A further study of the figures in Table I. reveals that during the past season at Blackwood the emergence period of Codlin Moths of the various broods was very much intermixed. On Graph No. 1 the weekly figures for the numbers of moths



Graph No. 1.



Graph No. 2.

caught are plotted. An examination of the graph reveals the probable occurrence of two broods, the maximum emergence of the first brood being about December 11th, whilst the maximum emergence of the second brood was approximately February 26th. There appears no evidence of a third brood, and young grubs were not at all numerous late in the season.

It will be noted also that many times, at irregular intervals, comparatively large numbers of moths emerged, and that Graph No. 1 does not reveal well-defined maximum emergence periods, as does the graph published in Bulletin No. 201. The abnormal seasonal conditions may have been the cause of this irregular emergence on the part of the Codlin Moths.

An interesting point that received attention this past season was the question whether birds interfered with the bait trap records by removing the trapped Codlin Moths. At various times small birds have been found drowned in the liquid, and it was thought they may have been after the moths. Twenty-five flower pot traps were used in one portion of the orchard, and each alternate trap was fitted with a wire-netting cover, and separate records made. The covered traps averaged for the season 51.5 moths per trap, and the uncovered 20.6 moths. These results are supported by previous experiments, so that there seems reason to think that there is a danger, where wire-mouthed traps are used, that the birds might upset the accuracy of the lure records for the proper timing of sprays. Graph 2 shows a comparison between covered and uncovered bait traps.

Experiments with Bandages.

All the trees in the various spraying tests were bandaged with the ordinary bag bandages made from wheat sacks. These were examined at approximately weekly intervals, and in Table II. the results are shown. It will be seen that 2,303 grubs were caught in 189 bandages, an average of 12.18 per bandage. The first grubs appear to reach the bandages towards the end of December, and large numbers accumulate there at the end of the picking season.

Table II.—*Weekly counts of Codlin Moth Grubs caught in Bandages, Blackwood*, 1933-34.

Date Examined.	No. of Grubs.	Date Examined.	No. of Grubs.
22/12/33	19	16/2/34	88
29/12/33	40	20/2/34	127
5/1/34	51	2/3/34	77
12/1/34	45	8/3/34	270
19/1/34	106	20/5/34	1,171
26/1/34	106	Total catch from 189 bandages	2,303
2/2/34	105	Average per bandage	12·18
9/2/34	98		

The number of grubs caught seems to indicate that though trees may be thoroughly sprayed, as these trees were in the tests, the use of a bandage is still necessary to maintain effective control.

Chemically treated bands were also used. These results have been the subject of a separate report.

Spraying Experiments.—Discussion of Results.

As previously set out, the spray schedules were arranged with the primary object of finding out whether the inclusion of white summer spraying oils in various ways in the spray schedules would give a more effective control of Codlin Moth than the arsenate of lead sprays at present mostly favoured by growers, and whether the standard dosages of arsenate of lead and white oil could, without impairing their effective control of Codlin Moth, be so reduced that their use would be

economically sound, and at the same time reduce the amount of arsenical residue to the limit of tolerance provided by health regulations both here and abroad.

Details of spray schedules are as follows:—

DETAILS OF SPRAY SCHEDULES, BLACKWOOD, 1933-34.

	* Lead arsenate in all schedules in powder form.	

The trees in the plots consisted mostly of Cleopatra Apple Trees, though some plots contained mixed varieties, *i.e.*, Cleopatra, Dunn's Seedling, Jonathan, and Scarlet Nonpareil. Most of the plots contained 12 trees, the smallest comprising 8 trees.

Computations of the results were made by actual weighing of all fruits, including windfalls, harvested from the total number of trees in each test. No distinction was made between actual entrances and stings, provided the blemish caused

by the sting rendered the fruit unfit for export. Computing results by weight gives a fairly accurate measure of the wastage due to attacks by Codlin, and can be considered a fair way in which to set a value on any particular spray schedule.

In the above spray programmes all spraying was thoroughly done, an ordinary motor spray pump being used. The spray was applied at a pressure of 170lbs. to 200lbs. with spray pistol grips and rod nozzle attachments. This type of delivery allows the operator to direct the spray from above as well as below, and ensures a better distribution of the spray fluid.

In Table III. the complete results are set out.

TABLE III.—*Results of Spraying Tests, Blackwood,* 1933-34.

Plot.	Spray Schedule.	Clean Fruit.	Codlin Fruit.	Percentage of Codlin Apples by Weight.
		Lbs.	Lbs.	
A	Lead arsenate with spreader four times, and one white oil and nicotine sulphate spray	4,026	120½	2·90
B	Lead arsenate twice, decreased quantity of arsenate, but with small amount of white oil in combination, and one white oil and nicotine sulphate spray	4,214	95½	2·22
B1	Lead arsenate twice, followed by three white oil sprays	2,095¾	32½	1·53
C	Lead arsenate twice, then alternate sprays white oil and lead arsenate, with oil spray last	3,537	66¾	1·85
D	Lead arsenate twice. increased quantity lead arsenate and white oil in combination twice, white oil and nicotine once	3,282½ 3,282½	45¾ 34¾	1·37 1·37
E	Arsenate of lead with spreader four times, fifth spray omitted	2,999½	251½	7·74
F	Repetition of Plot B with white oil No. 2..	3,505¾	157¾	4·31
G	Repetition of Plot C with white oil No. 2, and white oil and nicotine sulphate as last spray	4,025¼	171¼	4·09
H	Repetition of Plot D, with white oil No. 2	2,855¾	107½	3·66
I	Repetition Plots B and F, with white oil No. 3	2,772¾	96¼	3·35
J	Repetition Plots B, F, and I, with white oil No. 4	3,760	109½	2·83

A study of the results shows that there were really no significant differences in the degree of control obtained in Plots A, B, C, and D, which are comparable, as each contained the same number of Cleopatra apple trees. Actually the least percentage of infestation was shown by spray programme D followed by Schedule C, but the efficiency of either programme will depend on whether the extra clean fruit obtained will more than counterbalance the extra costs of added materials in each spray programme, and whether the arsenical residue was below export tolerance.

The question of comparative costs will be dealt with later, but it can be seen at a glance that the significant difference is so small that the extra value of clean fruit could not cover extra costs of spraying material, so that the amount of arsenical residue will be the determining factor in the value of these respective schedules.

Plot B consisted of 12 Jonathans, and in this schedule of 2 arsenate sprays followed by 3 oil sprays good Codlin control was obtained without any serious detriment to the colour of the fruit. The fruit was never highly coloured, but the same condition prevailed where white oils were not used, the hot, dry summer probably being responsible.

Plots E, F, G, H, I were mostly repetitions of previous spray programmes with various brands of white oils.

Plots E, F, G, H each contained 4 varieties (2 of each), and here again results are comparable. The significant differences are again small, with the possible exception of Plot E, where the last spray was omitted.

It would seem that this omission resulted in a heavier infestation in this particular plot.

Plots I and J consisted of 14 and 12 trees each of Cleopatra apples in a portion of the orchard removed from the other plots, and in which no bait traps were used.

The percentages of infestation in each case appear to show no significant differences. It can be claimed for the whole of the schedules that each gave very effective control as regards Codlin Moth, with the probable exception of Plot E, where the fifth spray was omitted

ARSENICAL RESIDUES.

The amount of arsenical residue remaining on the fruit at picking time after using any particular spray schedule is an important factor in deciding whether that schedule is a suitable one to adopt in general practice as a limit has been placed on the amount of arsenic that may be present on fruit at time of shipment. The amount of arsenic allowable is 0.01 grains per lb. of fruit estimated as arsenic trioxide (As_4O_6).

In order that the samples forwarded to the Director of Chemistry for analyses should be as nearly as possible comparable with the fruit submitted for shipment, they were subjected to the same treatment as export fruit, that is to say, they were handled in the same way from the tree to the packing shed, put through the grader, and again handled as if being packed.

The Department of Chemistry, to whom we are indebted for the analyses of the samples, reports as follows:—

Spray Schedule.	Arsenic as As_4O_6 in grains per lb. of fruit.
A	0·013
B	0·032
B¹	0·026
C	0·018
D	0·037
E	0·017

From the above figures it would seem that none of the spray schedules left an arsenical residue that would come within the export tolerance though A, C, and E are not greatly in excess of the allowable limit. The arsenical residue in B¹ is rather surprising as this schedule contained only 2 arsenate sprays followed by 3 oil sprays, and in a previous test showed only 0.005. Some slight alteration in A, C, E schedules could possibly be made whereby the arsenical residue could be slightly reduced without impairing their Codlin control efficiency.

Spraying Costs.

Costs play an important part in the selection of a spray schedule. The extra costs of spray materials in any schedule must be more than counterbalanced by the increased percentage of clean fruit at picking time before a new programme can be considered as economically sound. In Table IV. an attempt is made to show the comparative costs of Schedules A to E; 100galls. of spray mixture is used as a unit of comparison. Unfortunately a schedule was not included in which arsenate of lead only, with spreader, was used 5 times. In Schedule E, to make a comparison with Schedule A, the last spray was omitted, so that only 4 sprays were applied, and it cannot be used to compare costs. In the table, Schedule A has been used for purposes of comparison, though the last spray of oil and nicotine sulphate increased the cost of this schedule considerably. Taking into consideration the efficiency of the schedules and comparing costs, it will be seen that all of them were economically sound, though in B and D it would probably have been necessary to treat the fruit for arsenical residue before shipping. This added expense would more than counterbalance any increased profit from these schedules..

Table IV.—*Spraying Costs.*

Spray Schedule.	Arsenic Sprays. No.	Arsenic Sprays. Cost.	Arsenic Sprays. Total.	Oil Sprays. No.	Oil Sprays. Cost.	Oil Sprays. Total.	Nicotine. No.	Nicotine. Cost.	Spreader.	Total Cost.	Extra Cost over A
		s. d.	s. d.		s. d.	£ s. d.		s. d.	s. d.	£ s. d.	s. d.
A	4	3 2	12 8	1	4 1	0 4 1	1	3 5	3 0	1 3 2	—
B	2	3 2	6 4	3	4 1	0 12 3	1	3 5	1 6	1 6 8	3 6
	†2	1 7	3 2								
B¹	2	3 2	6 4	3	9 2	1 7 6	—	—	1 6	1 15 4	12 2
C	3	3 2	9 6	2	9 2	0 18 4	—	—	1 6	1 9 4	6 2
D......	2	3 2	6 4	2	5 6	0 11 0	1	3 5	1 6	1 11 0	7 10
	*2	2 4	4 8	1	4 1	0 4 1					
E	4	3 2	12 8	—	—	—	—	—	3 0	0 15 8	—

† 2lbs. per 100galls.
* 3lbs. per 100galls.

As the differences in percentages of clean fruit in the various schedules are so small, no attempt has been made to work out a profit or loss Table. Table IV. is included to show that from a costs point of view all the schedules were economically sound.

Summary.

All spray programmes gave satisfactory control of Codlin Moth last season.

No outstanding results could be claimed for any particular schedule as regards efficiency of control, all proving satisfactory.

Reduced quantities of arsenate of lead and white oil can be used without loss of efficiency.

None of the spray schedules reduced the arsenical residue below the export tolerance.

The inclusion of white oils in combination with arsenate, or following two arsenate calyx sprays, or used alternately with arsenate of lead, do not appear to give significantly better control in this season's experiments.

All spray programmes were economically sound, though in some the arsenical residue was somewhat high.

In conclusion, I would like to express my appreciation of the assistance received from the Assistant Orchardist (Mr. C. Pollitt) in the preparation of graphs, checking of results, &c., in connection with this report.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 5 *Test.*—Morning—1½ozs. wheat per bird.
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to October 31st, 1934.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to Sept. 30th, 1934.	No. Eggs Laid Month of Oct., 1934.	Total Eggs Laid April 1st, 1933, to Oct. 1st, 1934.
No. 1 test	10,555	848	11,403
No. 2 test	9,709	834	10,543
No. 3 test	9,465	860	10,325
No. 4 test	10,753	803	11,556
No. 5 test	5,374	574	5,948

IMPORTANT WEEDS OF SOUTH AUSTRALIA.

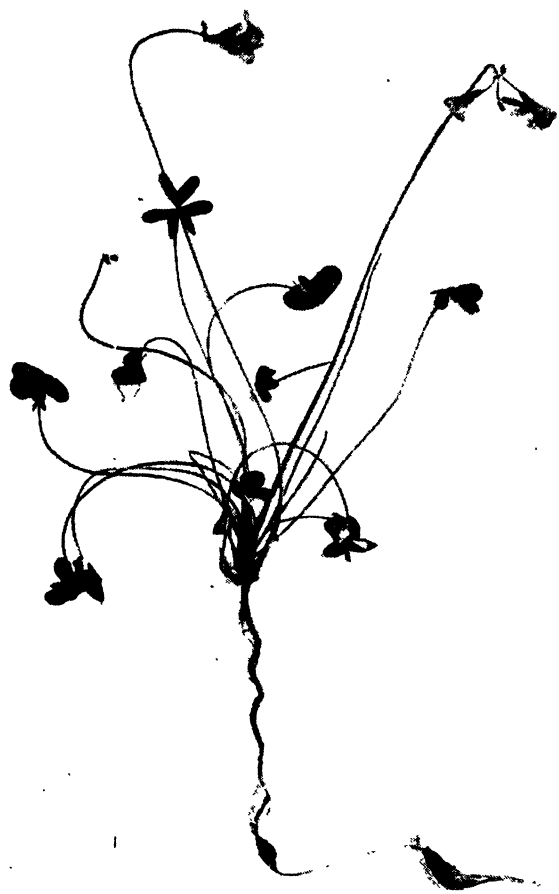
[By G. H. CLARKE, B.Sc., Botanist at the Roseworthy Agricultural College.]

No. 9.—SOURSOB.

Oxalis cernua, Thunb.

I. INTRODUCTORY REMARKS.

The Soursob or *Oxalis cernua* is an introduced bulb-forming plant, native to South Africa, but now so abundant and well known that it requires no introduction to the residents of this State. Few persons will be found to whom it is not



[*Photo. by A. R. Hickinbotham.*

Figure 1.—Photograph of entire plant of *Oxalis cernua* showing the underground parts, viz., rhizome, tuber, and developing bulb.

familiar, both as a weed and as a more than generous contributor to the rural colour scheme during the winter and spring months of the year. There are not many plants which thrust themselves upon one's notice as forcibly as the Soursob,

D

the sun-opened flowers of which impart their brilliant yellow colour literally to thousands of acres of land on the plains and hillsides, giving to the latter the appearance of being daubed and smeared with yellow paint by the brush of some Brobdingnagian artist. One may note, in passing, the remarkable scenic effects produced in this country by certain naturalised alien plants, and the kaleidoscopic changes in the colour of the landscape, brought about by the successive flowering of the different forms. In the large-scale process of yellowing of the countryside Soursob is assisted by the Capeweed (*Cryptostemma calendulaceum*), which forms dense mats in places, and whose somewhat paler flowers, formed close to the ground, add their quota of colour to the scene; in the hills there is the Common Broom (*Cytisus scoparius*), giving place, here and there, to the more sombre yellowish brown tints of the Furze, or Gorse (*Ulex europaeus*), an introduced leguminous shrub with spiny leaves. As the season advances, the yellows give place, in parts, to the violet blue of Salvation Jane, the "Patterson's Curse" of the Eastern States (*Echium plantagineum*), almost as lavish as the Soursob in its contributions of colour. Still later, in some parts of the hills, remarkable snow-white effects are produced by the Rock Lily (*Ornithogalum thyrsoides*).

Apart from its importance to agriculturalists as a weed, and to sheep-owners as a source of trouble with stock at certain times of the year, the Soursob is of interest for a variety of reasons. In fact, the plant is, in many respects, a remarkable one. Its general habit and life history both present unusual features; and in structure, no less than in physiology, it exhibits many peculiarities of interest and importance. Consequently, it is proposed to deal with *Oxalis cernua* at somewhat greater length than has been deemed necessary in the case of the weeds already described in the present series of articles, especially since not much has been written about the habits of the plant, and because a knowledge of these may prove to be of assistance in attempting its eradication and control.

*II. HISTORY OF THE PLANT.

The cultivation of species of *Oxalis* as ornamental plants appears to date from about the middle of the seventeenth century, the first introduced species cultivated in England being *Oxalis stricta* from North America in 1658. The next record is *O. speciosa* from the Cape of Good Hope, really a variety of *O. variabilis* of which the type was not introduced until about a century later. A very large number of South African species was brought to England towards the close of the eighteenth century, most of them during the last decade. There is evidence, however, that *O. cernua* was introduced before this, and that it was, in fact, grown during the early years of the latter half of that century. Under the name of *O. caprina* the plant was described and illustrated in colour in the Botanical Magazine (No. 237) in 1793, and it is stated there to have been "cultivated by Mr. Miller in 1757." By 1798 *O. cernua* was listed in European catalogues as a garden variety.

As regards its early history in South Australia, there appears to be little doubt that it was introduced intentionally as a garden bulb in the very early days of the colony. It was almost certainly brought from the Cape Province of South Africa, of which it is a native, though we have no record as to the person actually responsible. The plant appears to have been introduced prior to the establishment of the Botanical Gardens in Adelaide in 1855, and in the first catalogue of plants

*For much information dealing with the early history of Soursob in South Australia the writer is indebted to Mr. H. C. Trumble, M. Agr. Sc., of the Waite Agricultural Research Institute.

under cultivation there, issued in 1859, the Superintendent (G. W. Francis) recorded it amongst those grown. The late Mr. J. G. O. Tepper, writing in the "Garden and Field" in September, 1883, stated that the first he ever saw occupied a corner in a garden near Lyndoch some 30 years previously (*i.e.*, about 1853):—

"... close by a well, and highly prized by the occupiers. Later the cottage and garden were abolished, and the site with the adjoining land cultivated and sown with wheat, &c. The farmer tried all his skill in getting rid of them by ploughing, mowing, digging, hoeing repeatedly, with the result that, 20 years after, about 1·2 square chains were occupied by it, or a little more."

In the Flora Australiensis, of which the first volume was published in 1863, Bentham made no reference to *Oxalis cernua*, as he almost certainly would have done had it then become naturalised to any marked extent in this State; yet, at the time of Mr. Tepper's report (1883), the plant had already become regarded as a serious weed of fairly widespread occurrence. Evidently the plant escaped from cultivation some time between 1860 and 1880, most probably during the early sixties.

Incidentally, the weed during the nineteenth century was known as "Soursops," presumably on account of the watery or soppy nature of the foliage and stems; "Soursob" and "Soursobs," which nowadays are in more general use, are doubtless corruptions of the earlier name. In September, 1885, the "Garden and Field notes:—

"... a fellow who wants £500 to tell farmers how to kill the Soursobs or *Oxalis*. Well, now, we will tell how to do it and want no reward."

But despite the advice, gratuitous and otherwise, that has been given, and the measures that have been used for its eradication, Soursob now has a very extensive distribution throughout South Australia, and is widely spread, also, in Victoria. But it does not occur as a weed to any appreciable extent in the other States of the Commonwealth.

III. THE SYSTEMATIC BOTANY OF *OXALIS CERNUA*.

Botanical and Vernacular Names.—The name *Oxalis* comes from the Greek *oxus*, meaning "sour" or "sharp-tasting," and is due to the presence of organic acid in plants belonging to this genus; *cernua* means "nodding," or "drooping," and is on account of the sleep movements exhibited by the foliage and flowers of this species, which is referred to by some French writers as the "Drooping Oxalis" (l'Oxalis penchée). The name "Wood Sorrel" is very generally applied to plants of the genus *Oxalis*, but belongs in particular to the English species, *Oxalis Acetosella*. As regards *O. cernua*, the names most commonly applied to the plant are "Soursob," "Soursobs," or "Soursops," in this country, and "Bermuda Buttercups" in America.

The Family.—*Oxalis cernua* belongs to the *Oxalidaceae*, or Wood Sorrel Family, an assemblage of plants allied to the Geraniums and Pelargoniums grown in gardens, and characterised by having radially symmetrical flowers with five whorls each of five parts, a whorl of sepals, one of petals, two of stamens (rarely three), and a single whorl of united carpels. The Wood Sorrels differ from the Geraniums (family *Geraniaceae*) in certain structural details of the flower, and in the mode of dehiscence of the fruit. The stamens, in the *Oxalidaceae*, are united by their bases to form a ring surrounding the ovary, and the five styles of the carpels are free from one another; also, the fruit, though occasionally a succulent berry, is usually a capsule which splits along the dorsal suture of each of the five carpels, whereas, in the *Geraniaceae*, it usually breaks up into five one-seeded portions.

The family is made up of* 7 genera and approximately 870 species, all but 79 of the latter being contained within the large genus *Oxalis*. Of the other genera the largest is *Biophytum*, with 51 species of herbs distributed throughout the

tropics of Asia, Africa, and America, and of interest in having leaves which, like those of the Sensitive Plant (*Mimosa pudica*), are sensitive to the touch. Next comes *Sarcotheca*, with 15 species of trees and shrubs in the Malay Peninsula and Archipelago, and *Hypseocharis*, with 7 species of herbs belonging to Peru, Bolivia, and the Argentine. The three remaining genera are *Averrhoa, Eichleria,* and *Dapania,* each with 2 species, the first being trees or shrubs, and cultivated in the tropics for their berry fruits, the last two being natives, respectively, of tropical America and south-eastern Asia.

The Genus.—*Oxalis*, with approximately 791 species, is by far the largest and most important genus of the family. It is distinguished from the others by having flowers with 10 stamens, arranged in two whorls of 5, 5 carpels united when mature, dehiscent capsular fruits, and leaves usually with 3 digitately arranged leaflets. The number of leaflets is more than 3 in a few species, and it is sometimes reduced to 1, or even 0, in rare cases, the petioles then becoming expanded to form *phyllodia*, comparable with those of our Australian Wattles, and carrying on the function of the leaflets. Other characters are the regular flowers, the twisted petals, and the peculiar method of discharge of the seeds. These are provided with a seed coat (*testa*), of which the outer layer is fleshy and forms an aril which separates elastically from the inner hard layer, in such a way that the seed is forcibly discharged from the fruit.

A character very common in the genus, and met with also in some other families, is the occurrence of variation in the relative lengths of styles and stamens of the flowers. This variation does not occur in *Oxalis cernua,* but it is to be seen in a good many other species including one, *O. compressa,* which we shall describe in due course, and so is worthy of consideration at this stage. Examination of an *Oxalis* flower in section (Figure F., of coloured plate) shows that the terminal parts of the stamens and pistil occupy three distinct levels. Taking the Soursob flower as an example, it will be seen that the uppermost level is occupied by the anthers belonging to the inner whorl of stamens, and the lowermost level by those of the outer whorl, the middle level being taken by the stigmas, which terminate the styles of the pistil or carpels. This arrangement may be represented thus:—

Inner anthers
Stigmas
Outer anthers,

and appears to be constant in the case of *Oxalis cernua.* But in a number of other species it is possible to distinguish three types of arrangement, viz.—

(*a*)	(*b*)	(*c*)
Inner anthers	Stigmas	Inner anthers
Stigmas	Inner anthers	Outer anthers
Outer anthers,	Outer anthers,	Stigmas,

all occurring in different flowers of the same species of *Oxalis.*

This trimorphism of the flowers is connected with their mechanisms of cross-pollination, which is effected, in some species by bees, in others by butterflies. It has been found by experiment that a given type of flower, *e.g.*, a long-styled or (*b*) type, is most readily pollinated with pollen from another flower in which anthers occupy the same level as the stigmas of the first. In other words, a flower of the (*b*) type is pollinated more easily from (*c*) and (*a*) than from other (*b*) flowers; a (*c*) flower more easily from (*a*) and (*b*) than from other (*c*) flowers; and an (*a*) flower more easily from (*b*) and (*c*) than from other (*a*) flowers.

A few species of *Oxalis* produce, in addition to normal open flowers, a certain number of small *cleistogamous* flowers, which do not open and are self-fertile.

*According to Knuth in the *Pflanzenreich.*

The genus is represented in most warm parts of the world, but the two main centres of distribution are South Africa and tropical and extratropical South America. Two species are native in Australia, one, *O. corniculata,* being almost cosmopolitan, the other, *O. magellanica,* occurring in New Zealand and South America as well as in Victoria and Tasmania. In addition to the native ones there are some half-dozen introduced species in Australia. In this State the genus is represented by, in addition to the native *O. corniculata, O. cernua, O. compressa,* and *O. variabilis,* all belonging to South Africa.

With one exception the South African species are all bulbous perennials, either with or without an aerial stem, and with alternate or fascicled leaves and scape-like peduncles of flowers. On the other hand, some of the South American forms are tall and shrubby.

The Species.—In many of the bulb-forming species of *Oxalis* there is a differentiation of the bulb scales into outer ones serving for protection, and inner ones concerned in storage. Among this group of species, those in which the flowers are borne in false umbels constitute the section *Cernuae* of the genus. Within this section, those with yellow flowers comprise a subsection, the *Eucernuae,* which includes, amongst others, *O. cernua.* The characters which distinguish *O. cernua* from the other members of this subsection are (1) the presence of crowded bracts at the base of the umbel of flowers, (2) the stalked flowers, (3) the relatively robust habit of growth, (4) the rounded (not flattened) leaf-stalks, and (5) the presence of a few hairs on the undersides of the leaflets.

Description of O. cernua.—An almost glabrous perennial, with an annual, vertical, subterranean rhizome 2·8 mm. thick at the ground level but tapering below into a fine thread-like extension by means of which it is connected with the parent bulb, or with a fusiform translucent structure formed by tuberisation of one of its roots; rhizome with numerous hair-like adventitious roots, whitish, mostly unbranched, with 1 to several bulbils in the axils of scale-leaves, producing numerous leaves at the ground level, or sometimes extending horizontally for a short distance and bearing crowded leaves towards its termination; leaves all basal or subterminal, each with a short flattened leaf base, a long cylindrical petiole up to 13 cm. long, and three terminal digitate leaflets; leaflets obcordate, 2-lobed, 1·4 cm. broad, often marked with small purple spots; flowers yellow, drooping, 3-16 in umbels on long radical peduncles; sepals 6 mm. long with two orange calli at tip; petals 25 mm. long; inner stamens long, each with a staminodial appendage towards the base; styles short; capsule oblong-acuminate, rarely matured in Australia. Fl.—June-October.

IV. SOME PECULIARITIES OF *OXALIS CERNUA.*

1. *Delicacy of Plant.*—Among the outstanding features of the Soursob is the very great delicacy of the foliage and other parts as compared with those of most other plants growing in similar situations. There is an almost complete absence of woody fibre from the tissues, and of heavily cutinised membranes from the surface layers of the exposed parts. The softness of the tissues is associated with an exceptionally high water content, amounting to about 90 per cent. of the weight of the fresh plant.

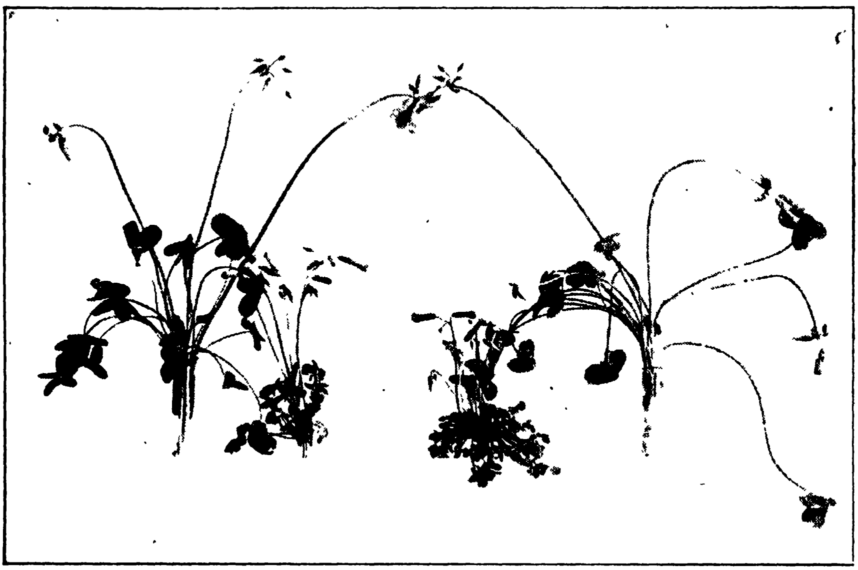
2. *Hardiness.*—Despite the extreme delicacy of its structure, the plant is exceptionally hardy when considered from the point of view of its ability to hold its ground in competition with other plants, and to spread from year to year. Within certain limits it is very resistant to adverse conditions; the smallest amount of moisture will enable the plants to live and continue to flower for days after they have been pulled out of the ground, and detached fragments in the ground have marked regenerative power. Moreover the plant appears to be adapted to a wide range of temperature and illumination.

3. *Reproduction.*—Another remarkable character is the almost complete abandonment, in this country at least, of seed production as a means of propagation, which, in *Oxalis cernua,* seems to be effected solely by means of the underground bulbils. The high order of efficiency achieved by this method of reproduction is

evidenced by the wide distribution of the plant throughout the State, the density of its growth on infested areas, and by the difficulty of coping with it as a weed in the garden.

4. *Bulb Formation.*—The production of bulbs is, in itself, an unusual character for a plant of the net-veined or dicotyledonous type. Bulb formation is common enough in the vegetable kingdom, but, with few exceptions, is confined to members of the parallel-veined or monocotyledonous series of families—Lilies, Amaryllids, Irids, &c.—plants far removed from *Oxalis* in the system of classification, and differing fundamentally both in structure and affinities.

5. *Tuberous Roots.*—Connected with the development of the underground bulbs, there is formed an especially interesting type of root system. Certain roots become swollen and tuberous due to the absorbtion and storage by them of large amounts of water. These tuberous roots are sweet to the taste, and contain a certain amount of sugar in addition to their large reserves of water; they are edible, and, in some countries are said to be boiled and eaten with milk. They appear to play an important part in the nutrition and development of the bulbs. Their stores of water render the young bulbs largely independent of soil moisture,



[*Photo. by A. R. Hickinbotham.*

Figure 2.—Photograph showing sun plants (centre) and shade plants of *Oxalis cernua*. Note the greater size, longer leaf-stalks and peduncles, and larger leaflets in the case of the shade plants. Compare also, in Figure 3, Nos. 16 and 18, with the other specimens photographed there.

and enable them to complete their development at leisure, so to speak, after the surface layers of the soil have become comparatively dry. But the tubers also have another and important function, in that they draw the bulb, and the lower part of the stem with its bulbils, down into the deeper and moister parts of the soil. They are, in short, *contractile organs*, and possess a very efficient and ingenious mechanism of contraction, which is brought into operation by the gradual drying of the soil. The behaviour of these contractile roots accounts, we shall see, for some of the difficulties associated with the eradication of Soursob; it also helps to explain the local spread of the plants.

6. *Sensitiveness to Light.*—Another noteworthy feature of the Soursob is its extraordinary sensitiveness to light, a sensitiveness which reveals itself in a number of different ways. Perhaps the most obvious effect of sunlight is that produced upon the flowers, which are wide open and face the sun during bright sunshine,

and become closed and drooping during darkness, and during dull, cloudy, or rainy weather. The leaflets also are expanded during the day and folded at night. These "sleep movements," as they are called, are affected, in response to variations in the intensity of illumination, by special movable joints termed *pulvini*, situated at the bases of the stalks of leaves, flower-clusters, and individual flowers, and at the junctions of the leaflets. Motor tissue occurs also along the main veins of the leaflets, and at the junctions of the lower parts of the petals, towards the base of the corolla tube.

Equally striking are the effects of different intensities of light upon the general habit of the plants, though, in this respect, *Oxalis* differs from most other plants in degree rather than in kind. Sun plants and shade plants of *Oxalis cernua* differ from each other markedly in size, length of stems, leaf-stalks, and peduncles, and in the size, texture, and hairiness of the leaflets. Moreover the effects of unilateral stimulation are well shown by differences in symmetry between plants situated, respectively, in the open and in the shade. The former are strictly radial as regards the orientation of their leaves in relation to the terminal bud of the stem, which is vertical in its direction of growth, whereas the latter assume, in varying degrees, a dorsiventral habit. In some cases the aerial part of the main stem extends horizontally along the ground for a distance of a foot or even more, and then ends in a crown of leaves, all directed upwards, that is, towards one side of the now horizontal axis (Fig. VI.).

A third indication of the sensitiveness of the plants to light is afforded by the wide range of intensities of illumination to which the Soursob appears to be adapted. Vigorous growth takes place both in strong sunlight and deep shade, the differences in size, form, and texture between the leaflets of sun plants and shade plants being doubtless correlated with this range of light receptiveness. It is possible that the assimilatory capacity of the leaves is increased in the case of plants growing in the shade; the lower surface layer, or epidermis, of the leaflets is composed of large papillate cells, which may have some condensing action on the diffuse light rays in dull and shady situations. One very noticeable feature of shade plants, in addition to those mentioned, is the paucity of flowers formed by them as compared with plants growing in sunlight. Light seems to be as necessary for the production, as it is for the opening, of flowers; in a shaded patch of plants, those situated on the outskirts are the only ones, usually, in flower.

7. *Acid Metabolism.*—Perhaps the most characteristic feature of the Soursob, in common with other species of *Oxalis*, and, in fact, of the family *Oxalidaceae*, is the sourness of the foliage and stems due to the presence of a well-developed organic acid metabolism, to which the plant owes its generic name, from which, in turn, is derived the name of the contained acid, viz., *oxalic acid*. This substance is poisonous, about half an ounce being regarded as a fatal dose for an adult human being, though death has resulted from as little as one drachm, and recovery from as much as an ounce and a half after prompt treatment. Even in the relatively weak concentrations in which it occurs in Soursob (about 0.7-1 per cent. of free acid), oxalic acid does, at certain times, cause poisoning when sheep, and especially ewes in lamb, are heavily grazed on Soursob pastures. Oxalic acid combines very readily with lime to form the insoluble calcium oxalate, and, when taken internally, is apt to cause profund disturbance of the calcium metabolism of the body by removing this element from solution in the blood and other fluids. Ordinarily the reserves of calcium in the body are such that sheep can ingest even large amounts of Soursob without suffering any ill effects. It is usually only at times when a big demand is being made on the calcium reserves that the system becomes highly susceptible to the poisoning action of a Soursob pasture. Such a demand exists in the case of pregnant ewes, in which large amounts of lime and phosphorus are needed for the development of the bones of the foetus; and so we find that ewes in lamb often show symptoms of Soursob poisoning on pastures on which other sheep remain unaffected.

An organic acid metabolism is rather common in some plants, notably in succulents, and the subject of acid formation has been considered in the past chiefly from the point of view of its relation to the succulent habit. It is well known that plants living under especially dry and arid conditions show certain structural differences from those inhabiting situations where the climatic conditions are more moderate. These structural modifications take place usually in one or other of two directions; in some plants there is an internal development of woody fibre and sclerotic tissue, combined with various devices for the reduction of transpiration or external water loss, such as, for example, the development of heavily cuticularised surface membranes, and of coverings of hairs, &c., the depression of the stomata or breathing pores of the leaves below the surface level, the reduction in size, and sometimes complete abortion of leaf-blades: a series of modifications resulting in a type of vegetation termed *sclerophyll.* In other cases the leaves or stems, or both, become thick and fleshy due to the internal development of large amounts of water storage tissue; the internal air-space systems are relatively small, the surface or epidermal layers showing varying degrees of cuticularisation, and sometimes themselves assuming the function of storing water. Such plants are called *succulents,* and are of two main kinds, *desert succulents* and *halophytic* or salt marsh types of *succulents.* Thus, desert and semi-desert plants may be of either the sclerophyll or the succulent type.

The physiology of desert succulents has led to a good deal of investigation and discussion, and there is an extensive literature dealing with the subject. It has been suggested that, whereas sclerophyll results from a type of metabolism in which sugars are converted into celluloses and other similar condensation products, succulence is the expression of a different kind of metabolism, one in which the sugars are transformed into pentosans such as mucilages and gums, substances with marked tenacity for water. But the known facts do not altogether support this view. It is found that succulence is a difficult thing to define, and that there is no single character by means of which it can be sharply distinguished from other types of habit. But it is recognised that the succulent habit is usually associated with certain marked peculiarities, not merely of structure, but also of metabolism and respiration.

Numerous investigations have shown that, in general, succulent plants possess a well-marked acid metabolism, and that there is a diurnal periodicity in the quantities of organic acids present in their tissues at different times of the day. Usually the acid content is lowest towards nightfall, and increases steadily during the evening, attaining a maximum value some time before sunrise in the early morning. During the day, under the influence of bright sunshine, the acids tend to disappear from the leaves, the amount present in the late afternoon being considerably less than at the commencement of the day. Associated with this diurnal change there are certain peculiarities in the respiratory gaseous interchanges; the carbon dioxide (CO_2) given off by the plants during darkness is much less in amount than the oxygen (O_2) taken in, whereas in normal respiration these values should be exactly equal. The reduced CO_2 output is accounted for in the case of succulent plants by the formation of organic acids, for which a supply of CO_2 is needed, that is to say, of the CO_2 formed in respiration only part is got rid of, part being retained and used in the synthesis of the acid, the decomposition of the acid during exposure to sunlight being accompanied by the formation of CO_2 as a by-product. Consequently, the organic acids present in the leaves of succulent plants are often regarded as constituting a reserve of CO_2 for purposes of carbon assimilation during the day.

Owing to the thin texture of its leaves and the great delicacy of its other parts, it is difficult to regard *Oxalis cernua* as a succulent plant in the usually accepted sense of the term, though it undoubtedly does show some tendencies in this direction. Unfortunately there are no data available as to the pentosan content of the plant, nor have we, as yet, any information as to the respiratory gaseous

exchanges. On the other hand the plant does possess a marked acid metabolism, and, as we shall presently see, there are grounds for believing that there is, in the course of this metabolism, a diurnal periodicity comparable with that found in plants of more typically succulent habit.

V. MORPHOLOGY AND VEGETATIVE LIFE CYCLE.

An account of the habits and vegetative life cycle of *Oxalis cernua* was given in 1914 by Ducellier, who made a careful study of the plant at the School of Agriculture at Maison-Carrée, in Algeria. According to Ducellier the life cycle in Algeria is distinguishable into three phases,—a first phase represented by the germination of the bulbil to produce, on one side, a vertical rhizome bearing buds, roots, and leaves, and on the other a crown of roots; a second phase corresponding to the tuberisation of one of the roots and the appearance of flowers; and a third and last phase, which begins with the appearance of a "primary bulbil" at the end of the tuberous root. During this last phase there takes place the transformation of the buds of the rhizome into "secondary bulbils," the "résorbtion" of the tuber ("tubercule") bringing about a natural displacement of one or more bulbils, the end of flowering, the fruiting of some capsules, and the destruction of the rhizome leading to complete independence of the bulbils. The following is a translation of the main substance of M. Ducellier's paper:—

Oxalis cernua, Thunb., a native of the Cape of Good Hope, is common in some cultivated areas in Algeria, *e.g.*, in the orangeries, where, during winter, it forms rather dense infestations. It spreads rapidly, and to such an extent that its presence is feared in gardens and orchards. It is found, to-day, not only in North Africa, but in Spain, France, Italy, Greece, Asia Minor, the Canary Islands, and in the Isles of Madeira. It is to be observed mainly near the sea, in places where the frosts are not severe, in valleys and on plains, where it seems to be perfectly adapted.

In Algeria, *Oxalis cernua* reproduces itself mainly by bulbils, which are mostly formed on the underground part of the stem. Seed is also produced, but in very small quantity.

The First Phase.—The bulbils are small conical structures with a rounded base, and consist of a series of white scale-leaves borne on a flattened axis, and arranged one inside the other with a very small terminal bud in the centre. These scales, which are of a shape becoming smaller towards the centre, are covered externally by two or three other brown scales thickened longitudinally towards the middle, and forming a rather resistant protective envelope. The bulbils vary greatly in size, the largest measuring up to 30 mm. in length, and 10 to 12 mm. in breadth, in rich garden soil. These bulbils weigh up to 2 or even 2½ grams when fully mature. The bulb-scales contain important starchy reserves which gradually disappear as the stem develops.

Germination of the bulbils begins when the earth is moistened by the first autumn rains; in fact, very little water is needed by these organs to produce stem and roots. The mature bulbs can be preserved for more than six months without appreciable loss of water (scarcely 1 decigram for the largest bulbils) if kept in a dry shady place. At the end of this time they will have produced short roots and stems.

In Algeria, it is towards the end of September, more generally in October, that the dormant life of the bulbils comes to an end. At this stage there emerges at the tip of the bulbil a slender stem which elongates rapidly, becoming gradually thicker as it approaches the soil level, where it may attain a thickness of 6-8 mm. The bud which terminates it expands and produces in a few days a rosette of trifoliate leaves.

The stem or rhizome is vertical; it bears numerous almost horizontal roots, and alternate scale leaves, each of which subtends a miniature bud which later grows into a bulbil. At the same time there appears, at the base of the parent bulbil, a series of roots which are stouter than those formed on the rhizome. They arise from the periphery of the axis, and emerge from between the lower bulb scales. These roots push their way obliquely into the soil for a distance which varies according to the hardness or richness, &c., of the soil. The length of the stem varies according to the depth at which the parent bulbil is situated; it does not seem to exceed 25-30 cm. even in places where the soil has been loosened to a great depth; it usually measures 10-15 cm., except, perhaps, in hard uncultivated ground, where it may be very short.

The Second Phase.—*Oxalis* quickly takes advantage of moisture in the soil, like all plants whose root systems develop in the superficial layers of soil. In order to appreciate this fact it suffices to dig carefully among a clump of the plants, towards the middle of November, for example: one is surprised to find, immediately below the bulbil, a tuber formed by the swelling of one of the roots inserted on the periphery of its flattened axis.

[*Photo. by A. R. Hickinbotham.*

Figure 3.—Photograph showing various stages in the development of *Oxalis cernua* from the bulbs and bulbils. Nos. 16 and 18 are shade plants from loose garden soil, all the rest are sun plants from hard uncultivated ground; 1-4, ungerminated bulbs and bulbils; 9-10, early germination stages; 5-8, development of the tuber; 12-16, contraction of the tubers; 17, showing branched rhizome; 18, shade plant from garden soil showing large tuber and very long thread-like rhizome; 19-20, germinating bulbs opened out to show the rhizome arising in the axil of a bulb-scale and bearing rudiments of bulbils.

Certain of these tubers measure up to 35-40 cm. in length, and 12-15 mm., sometimes, in thickness, when the plant is growing in loosened and fertile soil, *e.g.*, in vineyards and orchards. Plants may be found with two or more tubers, but this is rare, except where the plants have been injured, *e.g.*, by cultivation implements. The rhizome can, in fact, be broken, bruised, or completely severed from the tuber and bulbil; on the fragments of the rhizome there appear buds, some roots, even those of the rhizome, begin to swell and develop into tubers.

The tuber of *Oxalis cernua* resembles a small, much elongated salsify; it is transparent, and one can easily see, in the centre, the fibrovascular bundles of the root from which it developed, forming a white line traversing it longitudinally. The tuberisation of the root begins soon after the appearance of the leaves.

The tubers are very watery, soft, and brittle. Their taste is sweet. There is no doubt that these tubers, swollen with water of which they contain as much as 90 per cent., constitute a reservoir from which the plant will later draw the necessary materials for the development of its bulbils and fruits.

We shall note, in passing, the disproportion existing between that part of the stem near the tuber, and the tuber itself; it is sometimes in the ratio of 1 : 20; in fact, certain tubers attain more than 15 mm. in diameter in fertile soil, while the lower part of the stem, situated in the bulbil, does not measure more than ½ mm. in thickness. This peculiarity means that the stem separates from the tuber with the greatest ease at the slightest traction exerted upon it. One can pull up the stem without suspecting the presence of equally large tubers. The development of the tubers marks the end of the second phase of the growth of the plant, by which time the original bulbil has also produced the stem with both leaves and flowers.

The Third Phase.—In Algeria, *Oxalis* continues to grow during winter, and, if its development is carefully followed, there is to be seen appearing, below the bulbil and almost at the summit of the tuber, a bud, almost imperceptible at first, but soon enlarging rapidly. It is a new bulbil, which can grow to the size indicated above. As the bulbil grows the tuber empties itself gradually, and disappears after a short time, leaving in its place a small blackish shrivelled body, which also disappears in the course of the year. The tuber of *Oxalis cernua* is ephemeral; it develops and is "resorbed" in a short time, 2-3 months in Algeria, if the winter is mild (Fig. IV.).

After the appearance of the first bulbil, which may be called the *primary bulbil*, and before it has reached its full size, others develop on the stem, smaller ones which may be called *secondary bulbils.* The buds situated in the axils of the scale leaves of the stem are mostly transformed into bulbils, especially those nearest to the rosette of leaves. Their number and size (Fig. IV.) varies much, and evidently depends on the moisture present in the superficial layer of soil, and the nutritive materials to be found within reach of the plant. Under favourable conditions it is possible to count 20 bulbils per plant. One may well imagine the number present in the soil at the site of a patch of *Oxalis* plants.

As the wet season passes the bulbils steadily ripen; at first white, they later assume a chestnut-brown colour when fully mature. The taste of the bulbils is quite different from that of the tubers. Instead of being sugary like the last, they are acrid. Their acridity, disappears, however, on boiling.

Oxalis cernua flowers early on the Algerian littoral, from about the end of December. The flowering continues right up till the end of March or April, according to the weather conditions. The number of flowers varies greatly; certain plants produce many hundreds of flowers, while others do not flower at all. In all cases very few of the flowers are fertile; one or two seeds are rarely found in the half-developed capsules.

When the substances stored in the tuber make their way towards the bulbils, the tuber shrinks and becomes pushed in like a concertina of which one side is kept fixed. The lower part of the tuber being, in fact, fixed in the soil, the tuber, in gradually contracting, slowly draws downwards the stem, which elongates and becomes stretched out below into a very delicate thread.

Likewise, the bulbil fixed at the upper part of the tuber travels a certain distance, as will readily be understood, since the remains of the old bulbil, near which it is formed, does not change its position. This distance equals, in some cases, 25 cm. Moreover, the displacement of the bulbils can be verified in another way, for there is left, in the soil, and very distinctly preserved, the nearly cylindrical imprint of the original place occupied by the tuber when at its maximum size.

Of the other bulbils, one or two situated in the lower part of the stem follow and travel a certain distance less than that traversed by the first. These bulbils evidently cease to move when the tuber is exhausted. This constitues a peculiar habit, uncommon, it seems to us, among plants, of the displacement of organs concerned in multiplication. This method allows the Oxalis to invade, little by little, large areas, even when it does not produce any seeds, as is the case with the variety with double flowers,*

*A form with double flowers is very common in the Mediterranean region, but does not occur in South Australia.

which does not form fruits. The displacement of the bulbils takes place obliquely, almost horizontally in some cases. There are, then, always some bulbils which move away from the centre of a clump of plants. We shall recall that the seeds of *Oxalis* are projected far from the capsule which contains them by their arils during dehiscence. *Oxalis cernua* thus possesses two natural methods of propagation independently of the transport of bulbils and seeds by man.

At the onset of the first warm weather, in April on the Algerian littoral, the leaves begin to disappear, their leaflets becoming detached and falling together with the petioles, followed then by the peduncles. If the axillary buds are not transformed into bulbils they disappear (*Oxalis cernua* can form aerial bulbils). The rhizome and the remains of the tuber are the last to disappear. At the end of some time the decomposition of these materials is complete, and, in place of a plant of *Oxalis cernua*, there are only bulbils placed at variable depths, and quite independent of one another.

The life history of the plant in South Australia appears to correspond very closely with that in Algeria, as described by Ducellier, when due allowance is made for the reversed seasonal conditions in the Southern Hemisphere. Here, as in Algeria, germination of the bulbils and early growth follows the first autumn rains, and so takes place, in this country, during April and May. The appearance of the plant is heralded by a peculiar sponginess of the ground, due to the upgrowth towards the surface of the innumerable stems formed by the germination of the underlying bulbils. The stems push their way upwards, and many of them show signs of having encountered much resistance in the course of their ascent through the soil. The surface of the ground becomes covered with small pimple-like elevations, and it feels springy when walked upon. Examination of one of these pimples reveals the terminal leafy bud with its leaflets folded in repose, just below the surface of the soil. Soon it bursts through and unfolds its rosette of leaves. From now on growth continues and, by the end of June, flowers have begun to appear, and these become more numerous and conspicuous during the succeeding months. The tubers, which have meanwhile begun to develop, reach their maximum size usually during July, and, by the middle of August, most of them have begun to contract. Growth and flowering continue during the spring, but the plants die off rapidly after the onset of the dry weather, except in a few favoured situations. By the end of October most of the Soursob has disappeared, the entire period of growth occupying about 6 months of the year.

Though Ducellier describes some of the tubers as being about 15in. long, they are usually smaller than this. Most of those observed by the writer were under 8in., usually 4-6in. in loose garden soil and 1-3in. in hard ground. In a number of cases observed one of the lateral roots of the tuber was itself tuberous, and tuberisation of one of the adventitious roots of the rhizome was also noticed in one instance.

The rhizome was unbranched in the great majority of the specimens examined, but in a few cases it bore 1, or rarely 2, lateral branches. Evidently the buds of the rhizome can develop either into bulbils, or into stems similar to the first.

As regards the bulbils, there is one point, it seems to us, that Ducellier fails to emphasise sufficiently, and that is the distinction between what he respectively terms the "primary" and the "secondary" bulbils. There is an important morphological difference between these, and a still more important physiological one. The first is that they arise from axes of different degrees, the "primary" bulbil from the greatly shortened bulb axis which, since it represents the main stem of the plant, is an axis of the first degree; the "secondary" bulbils from the vertical rhizome or stem, which is a lateral branch of the first, and, consequently, an axis of the second degree. Since the "primary" bulbil is usually larger than the "secondaries," it will be permissible, for purposes of greater emphasis, to distinguish them respectively as the *bulb* and *bulbils,* reserving the latter term for the "secondaries" alone. Moreover, the bulb appears to be terminal whereas the bulbils are lateral structures. The physiological difference is even more important. The bulbils are organs of multiplication; they give rise to new plants or

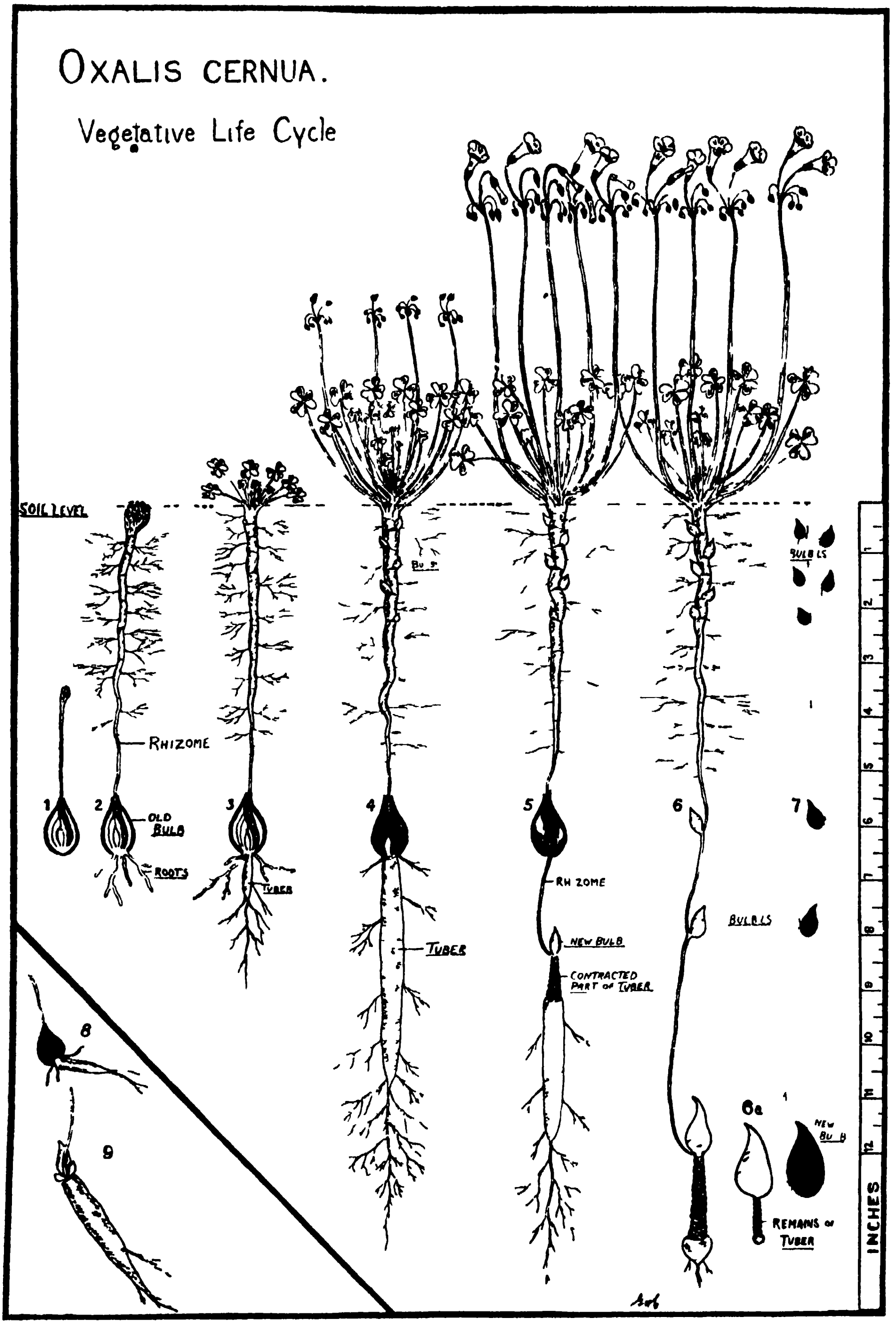


Figure 4.—Diagram to show the vegetative life cycle of *Oxalis cernua* (1) Germination of bulb, upgrowth of rhizome and terminal bud; (2) formation of roots at base of bulb, appearance of shoot at surface; (3) commencing tuberisation of one of the bulb roots; (4) tuber fully formed; (5) contraction of tuber and descent of bulb and rhizome in the soil; (6) contraction almost complete, enlargement of bulb and of the bulbils of rhizome; (6a) contraction complete; (7) death of plant, bulb and bulbils left in soil; (8) germinating bulbil showing oblique direction of tuber in soil (see also No 7, Figure 3); (9) tuber with one or two small bulbs below the larger terminal bulb

individuals. Not so the bulb; it merely perennates the plant, that is, it continues the growth of the one plant or individual during each successive season. The Soursob is a perennial plant, but the part appearing above ground is merely a lateral branch which dies at the end of the growing season; the truly perennial part of the plant is in the soil, and is, in fact, the bulb itself. The bulb formed at the end of the growing season was already present, in a primordial form, in the parent bulb or bulbil which underwent germination at the commencement of that season; and it contains the primordium of the bulb which will form at the end of the next season. Without embarking upon a philosophical discussion, we may accept *organic continuity* as a criterion in deciding whether a given collection of living units constitutes a single individual, or a number of separate individuals. If the units are all connected together by living matter without any break of continuity, then we may regard the system as one individual; if no such continuity exists, then each unit is an individual separate from the rest. In terms of this conception the bulb represents the continuation of one perennial plant or individual, whereas the bulbils, once they are separated from the parent plant, represent the commencement of a new series of individuals.

If, then, we regard the life cycle as beginning with the germination of a bulbil, it is possible that *Oxalis cernua* does not flower during the first year of its growth. Some of the plants, Ducellier points out, do not produce flowers, and these plants arise from small *bulbils. It seems likely that these non-flowering forms may represent the first year's growth of plants formed from bulbils, and that the larger flowering forms are older plants developed from bulbs.

This distinction between bulbs and bulbils may explain some of the difficulties met with in attempting to eradicate Soursob by cultivation methods. Most of the bulbils are formed in the upper 3in. or 4in. of soil, though one or two are usually found at a deeper level. The bulbs, however, are situated much more deeply, being 6-12in. or so from the surface, below the level, not only of cultivation, but even of deep ploughing. If the cultivation methods have not prevented the formation of these bulbs, the re-appearance of the plants the following year is inevitable. The presence in the tubers of sugars, in addition to water, makes it far from impossible that maturation of the bulbs may be effected even when the surface growth is destroyed, once the tubers have been allowed to reach their full size. These considerations suggest that eradication measures should aim at preventing these tubers from contracting, and so from withdrawing, with their developing bulbs, out of reach of the cultivation implements.

This does not necessarily mean that surface cultivation is useless. Even if the tuber does contain sufficient reserve material to develop a bulb when the aerial parts have been severed, the bulb so formed would doubtless be smaller than otherwise, and the resulting plant would probably be less vigorous. The deeper the level at which the bulb is situated, the greater the amount of energy that must be expended in order that the resulting shoot may reach the surface. By reducing the size of the bulbs developing in the deeper parts of the soil, surface cultivation at the right time would undoubtedly weaken, if it could not eradicate, the older plants in an infested area.

It has been stated that, in addition to the bulbils formed in the upper part of the soil, one or two are usually formed lower down. The primordia of these appear at a very early stage, and are visible as small white dots on the lower part of the stem when the germinating bulb is opened out. Their development, however, takes place rather slowly. The lengthening of the stem, which accompanies the contraction of the tuber, affects the part below these primordia more than the rest, and, as the tuber detaches itself from the old bulb scales and

*Explained in the legend to one of Ducellier's illustrations.

descends, carrying with it the young bulb and the fine thread-like extension of the stem, these bulbils often remain inside the empty shell of the old bulb, which retains its shape and remains fixed in the soil at the original level. As the bulbils grow they become imprisoned within the old bulb scales which form a kind of protective capsule inside which the bulbils complete their development. This explains why a number of the old bulbs, when opened, are found to contain two or three whitish bulbils joined together by a variable length of slender stem.

The rhizome or stem arises as a lateral branch of the orginal bulb axis, being formed in the axil of one of the bulb scales. In the event of injury to the rhizome, we should expect another to be formed in a corresponding position in the axil of another bulb scale. This has not actually been observed, but is doubtless true. But, in some tubers which had been kept in water in the laboratory for about 10 days, there appeared, just below the terminal main bulb, one or two smaller lateral bulbs, evidently from buds in the axils of the innermost scales (Fig. IV., 9).

VI. MEANS BY WHICH *OXALIS CERNUA* IS SPREAD.

As regards the natural spread of *Oxalis cernua*, the possibility of seed formation must be borne in mind, though it is stated to be rare in this country, and has certainly not been observed by the writer. But it is obviously impossible to be sure that it does not take place at all. Even the production of only one or two seeds by each plant in flower would mean a not inconsiderable quantity of seed formed in the case of an area densely infested with Soursobs. Seed produc-

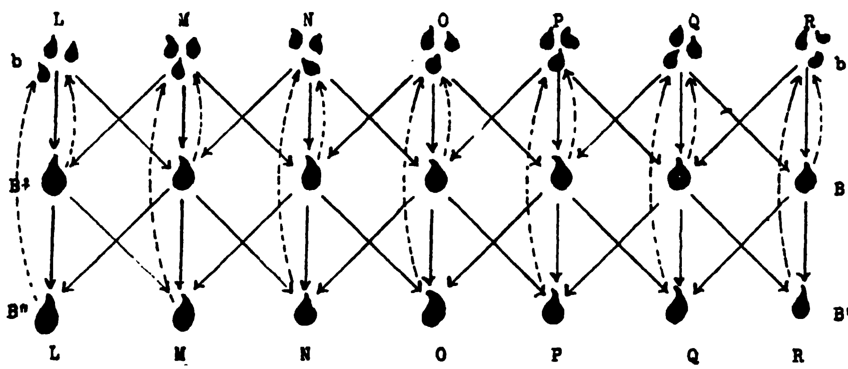

Figure 5.—Diagram to show method of local spread of Soursob due to the traction exerted on the bulbs by the contractile roots. The straight arrows represent directions of traction in the soil; the curved (and dotted) arrows indicate the formation of bulbils by plants produced on germination. (See text).

tion cannot, therefore, be ruled out as an unimportant factor in causing the spread of the plant, though we have no positive evidence of its occurrence. The seeds, when formed, are small and light, and are forcibly expelled from the capsules by the elastic separation of an outer fleshy layer (*aril*) of the seed coat.

The method of local spread due to the contraction of the tubers has been explained by Ducellier, and may be represented by the accompanying diagram (Fig. V.), which assumes, for purposes of simplicity, three directions of traction for each set of bulbils and bulbs, viz., vertically downwards and obliquely downwards, either to the right or to the left, as indicated by the arrows. The dotted lines represents the formation of bulbils by plants developed from the bulbs indicated in the diagram.

We may suppose a small group of bulbils to be situated near the surface of the soil (level b) just below the point O, that is, in the position Ob. The plants formed by these will reach the surface at O; but, when their tubers begin to contract, the new bulbs will be pulled downwards, either straight down, or

obliquely to the right or left, and so will come to occupy positions corresponding to OB′, PB′, or NB′, the plants formed from these on germination appearing at the surface at the points O, P, and N, respectively. These plants will produce bulbils below the surface at these points; but their developing bulbs will be drawn by the contraction of the tubers into positions corresponding to the positions MB″, NB″, OB″, PB″, and QB″, and so on, each set of bulbils formed near the surface being the starting point of a similar series of changes.

Another factor in bringing about a local spread of the plants is suggested by the dorsiventral habit of the stems of certain plants growing in the shade. The stem, in these cases, bends from the vertical to the horizontal, and any bulbils formed on the horizontal part will naturally be deposited some distance away from the original vertical axis of the rhizome (Fig. VI.).

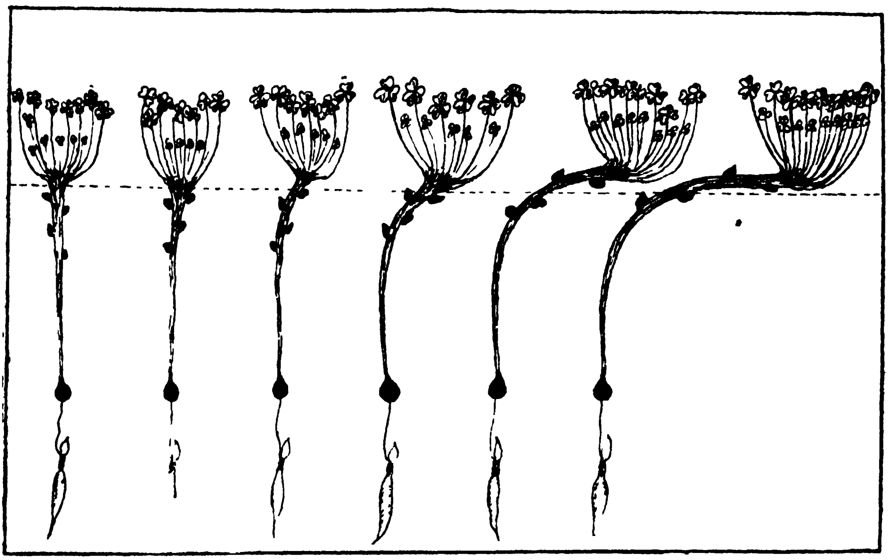

Figure 6.—Diagram to show method of local spread in the case of plants growing in the shade, and the assumption by the stem of a horizontal direction of growth.

By these methods there takes place a gradual increase in the size of isolated patches of Soursob in situations not subject to disturbance of the soil. There occurs also a steady increase in the number of individual plants within the area, and, by the descent of more and more of the bulbs into the deeper layers of the soil, a gradual consolidation of the ground occupied. But the spread in this way would take place rather slowly, were it not assisted by other factors tending to bring about a wider distribution of the bulbils, and their transport to new situations. Of these factors the first has been the intentional distribution of the bulbs as garden plants before the potentialities of Soursob as a weed were recognised, and the second was, doubtless, the unintentional spread of the plants locally, due to carelessness and to unsuccessful attempts at eradication. Probably the most important factor responsible for the subsequent spread of the plants throughout agricultural lands has been the use of farm implements in the ordinary processes of ploughing and cultivation, &c. Given a few patches of Soursob in a field, the bulbils formed by these are certain to be spread over a wider area during cultivation. An important point here is that the bulbils are abundantly present in the soil during the dry summer months, when the plants themselves are not in evidence, and can be spread much more effectively at this time than during the growing period of the plants. The appearance of plants in clean paddocks has doubtless been brought about in many ways, such as by the introduction of bulbils

with mud clinging to the farm implements, or to the feet of animals. Wind may play some part in the process, since the bulbils are very light, and are brought to the surface in large numbers during cultivation. The occurrence of plants along fences and other breakwinds suggests a possible role of wind in this connection. It is impossible to enumerate all the possible means by which the transport of bulbils has been effected; but it seems probable that much of the spread has been brought about unconsciously by the transport of bulbils in earth, &c., at a time when the plants were not visible above ground.

VII. THE CONTRACTILE ROOTS OF *OXALIS CERNUA*.

The tuber or contractile root is formed by the enlargement of one of the slender roots which arise from the base of the bulb or bulbil during its germination. The anatomical structure of the tuberous root does not differ essentially from that of other such roots, the main difference being in the relative proportions of the tissues present. The water-conducting tissue (*xylem*) is small in amount, whereas the region normally concerned in the translocation of food substance (*phloem*) is very large and, in fact, makes up the greater part of the substance of the tuber. Cross section of a tuber shows, when viewed under a microscope, a small centrally-placed xylem strand, consisting of a few primary vessels interspersed with parenchyma and surrounded by a number of secondary xylem groups separated by parenchymatous intervals, the whole forming a slender strand, which traverses the root in a longitudinal direction, and is distinctly visible to the naked eye through the translucent outer tissues of the tuber. Immediately outside the xylem is a layer of cambium which, however, does not appear as a regular layer in the expanded tuber. But it is to the repeated divisions of the cells of this layer that the tuberisation of the root is mainly due. On its outer side the cambium cuts off layer upon layer of thin-walled cells forming a wide phloem tissue, which is at first more or less uniformly composed of small cells with dense living contents. But as these phloem cells are pushed outwards by the subsequent divisions of the cambium cells they lose their uniform appearance. The parenchymatous elements of the phloem become greatly enlarged due to the absorption of water, while the other constituents of the phloem (*sieve tubes* and their *companion cells*) remain small, so that the phloem comes to consist of a wide parenchymatous tissue with scattered nests of sieve elements traversing it longitudinally and forming a branching network of slender strands, the meshes of the network being occupied by the parenchymatous elements. The tissue is covered externally by a number of layers of flattened cells forming the periderm or outer skin of the tuber. The periderm forms a tough membrane, and is relatively impermeable to water; it plays an important part in the subsequent contraction of the tuber.

The parenchymatous phloem constitutes the main contractile tissue of the root. In the fully expanded tuber it consists of cells all turgid with a watery sap, the outermost cells being firmly attached to the periderm, while the innermost ones are pressed against the cambium and xylem.

The mechanism of contraction is very simple, and, in *Oxails cernua,* appears to be identical with that described by Thoday in the case of *Oxalis incarnata.* As Thoday points out, the theory of root contraction most generally accepted, namely, that due to De Vries, in 1880, that it is caused by growth in thickness, the transverse expansion being accompanied by longitudinal shrinkage, is not applicable to the case of *Oxalis.* In *Oxalis incarnata,* and also in *O. cernua,* the contraction is brought about by shrinkage in all dimensions of the contracting part of the tuber, due to the removal of sap from the cells of the contractile tissue, the process being assisted by the drying of the soil The contraction takes place

progressively, commencing at the top of the tuber and extending downwards, the contracted portion becoming wrinkled and reduced in diameter. Longitudinal sections through the wrinkled part of the tuber show "an alternation of transverse plates of turgid cells with layers of collapsed cells which appear as crushed between the still turgid layers."

Ducellier likens the process of contraction to the pushing in of a concertina, or to the collapse of the bellows of a camera. The side walls of the bellows are strengthened by the method of folding along certain planes, in such a way that

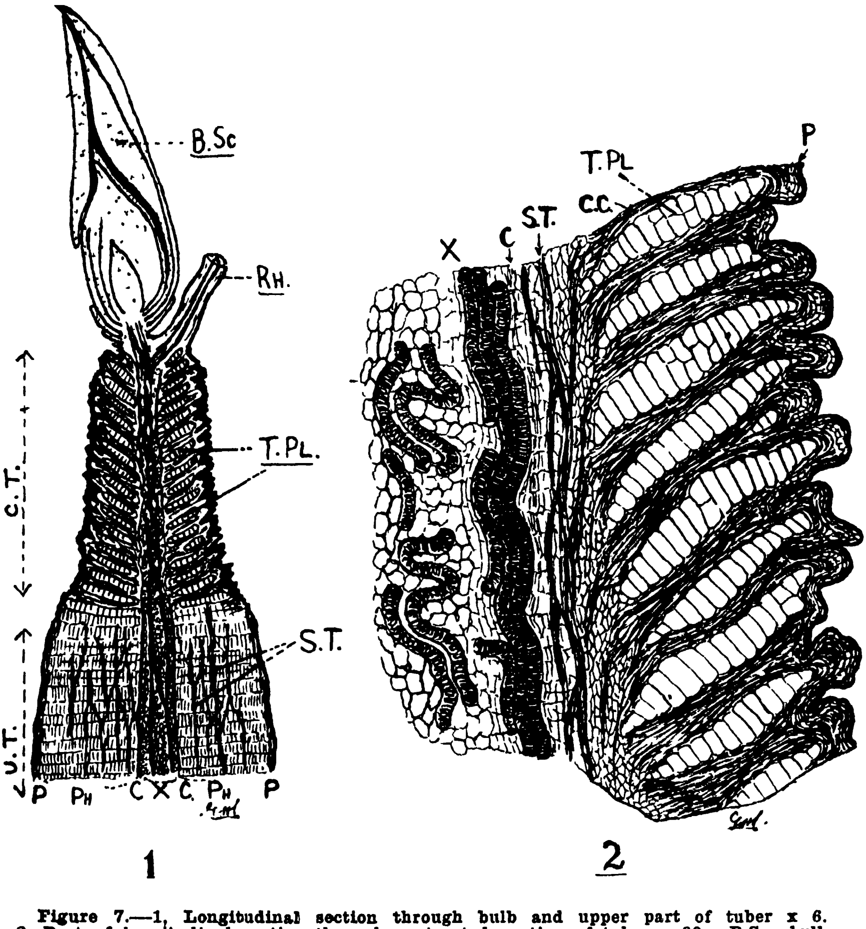

Figure 7.—1, Longitudinal section through bulb and upper part of tuber x 6. 2, Part of longitudinal section through contracted portion of tuber x 30. B.Sc, bulb scale. C., cambium. C.C, crushed cells. C.T., contracted portion of tuber. P., periderm. PH., phloem. RH., rhizome. S.T., sieve tubes. T.PL, plates of turgid cells. U.T., uncontracted portion of tuber. X., xylem.

the walls do not collapse inwards at these points; these planes behave as a series of rigid parallel frames, arranged at regular intervals and at right angles to the direction of contraction. During contraction these frames are approximated by the collapse of the intervening more flexible parts of the walls. Collapse of the bellows takes place when the two ends are pushed closer together; but if the apparatus is air-tight, it can also be effected by sucking air out of its interior, and so causing it to contract. This, in fact, is the type of mechanism responsible for the shortening of the tuber. In the fully expanded condition the parenchyma cells of the phloem are all filled with liquid; this sap is gradually withdrawn, by the

developing bulb and stem, from certain zones of cells which alternate in position with others which retain their sap. The collapse of the cells resulting from the loss of their sap causes the periderm or skin to be pulled inwards, so that the zones of still turgid cells are thereby approximated, like the rigid frames in the case of the bellows. In short, the contraction of the tuber is caused by the removal of the watery sap from phloem cells in certain transverse planes, and its retention by cells in planes which alternate with the first. The latter form plates of turgid cells, which are at first transverse, but subsequently become oblique due to "external friction resisting contraction more than the xylem resists compression."

Accompanying diminution in length there takes place a reduction in diameter of the contracted portion of the tuber; if the two ends of a fully contracted root are forcibly pulled apart, the periderm tissue becomes detached from the turgid plates of cells, and may be stretched to more than double the original length of the tuber.

VIII. THE ACID METABOLISM OF *OXALIS CERNUA*.

Oxalis cernua and the Succulent Habit.—We have already remarked that the habit of *Oxalis cernua* presents rather marked differences from that usually regarded as typical of succulent plants, namely, thick fleshy leaves or stems, heavily cutinised surface membranes, small internal air-space systems, high pentosan content, acid metabolism, &c. The impossibility of defining succulence, however, by any one single character makes it difficult to assign a position to *Oxalis* in this respect. The plant does show some tendencies in the direction of succulence; the stems are thick and soft, and, like the tubers, contain a large amount of water; the leaflets of plants grown in strong sunlight show a slight fleshiness, and their cuticular layers are thicker than in the case of plants growing in shade. If succulence is to be looked upon as a departure from the sclerophyll structure, it would be difficult to find a plant, outside of the fresh water Algæ and other aquatics, of which this departure is so marked a characteristic. The percentage of dry matter in the plants is surprisingly small, being usually less than 10, both in the tops and in the roots; thus, excepting the bulbs, the entire plant contains rather more than 90 per cent. of water.

Most succulent plants contain a certain amount of woody fibre and other sclerotic material, sometimes rather large amounts of it; indeed, some important fibre plants, *e.g.*, *Agave*, are of the succulent type. But in *Oxalis cernua* there is an almost complete absence of such tissue, the only woody elements present being the vessels of the xylem, which are concerned solely in water conduction, and even this tissue is small in amount. In view of the ability of the stems to push their way through hard ground, it is interesting to note that the plant seems to depend for its mechanical requirements, entirely upon the tugor of thin-walled parenchyma cells.

The marked difference in texture between the aerial parts of Oxalis and those of succulents, is to be explained, perhaps, by the bulb-forming habit of the former plant. By assuming a mode of life in which the aerial growth takes place during the wet season of the year, the dry period being passed as a dormant subterranean bulb, Oxalis has doubtless effected many structural economies that would be impossible in the case of a plant living above the ground during the dry summer months of the year. It is possible, therefore, that the habit of Oxalis represents an advance on that of the true succulents, in that the structural modifications normally associated with succulence have been rendered unnecessary by the adoption of a particular mode of life.

Diurnal Periodicity in Acid Formation.—The formation of large amounts of organic acid by Oxalis suggests a type of metabolism akin to that of succulent plants. The latter are usually rich in organic acids, the amounts of acid present in their leaves, however, being subject to variation at different times of the day.

In most cases the acidity rises during the evening and falls during the day, the process being accompanied by deviations from the normal unity value of the respiratory (CO_2/O_2) quotient, owing to the fact that part of the CO_2 formed in respiration is utilised in the synthesis of acid during the night. This diurnal periodicity is influenced by a number of factors: for instance, it has been shown that the amount of acid formed during the evening depends upon the illumination of the plants during the preceding day.

In view of the very dense growth made by Soursob, and its tendency to smother other herbage in a pasture, and so to form an unduly large proportion of the material consumed by grazing stock, it seemed to the writer to be of interest, and perhaps of importance, to ascertain whether the oxalic acid content of the plant were subject to a diurnal change comparable with that occurring in succulent plants. Since oxalic acid is poisonous, and occurs in Soursob in quantities sufficient to cause serious symptoms, and even mortalities, among stock at certain times of the year, it might be of value to know whether the plant is less poisonous at some times than at others, and, if so, the amount of variation in toxicity, and the times of minimal and maximal acid concentration.

To obtain information on some of these points, determinations were recently made, at Roseworthy College, of the total oxalate content of leaves gathered from plants at different times of the day. In some previous analyses, undertaken with a different purpose, Hickinbotham and Bennett found that approximately one-half of the total oxalates exist in the plant as free oxalic acid, the remainder in an insoluble form, probably as calcium oxalate. As these authors pointed out, the total oxalate content is of more importance, from the point of view of toxicity, than the amount of free acid present, since calcium oxalate may be decomposed during digestion with the liberation of free oxalic acid. For this reason the total oxalates were determined rather than the acid itself.

The analyses were performed by Mr. K. Woodroffe, R.D.A., under the direction of the writer's colleague, Mr. A. R. Hickinbotham, B.Sc. In all, two series of determinations were made, the one towards the latter end of June, 1934, the other two months later, during the final week of August last. In the first series the analyses were performed in triplicate, the figures given being the average results of the three samples of each set of leaves taken; in the second series they were done in duplicate, the results again being averaged:—

TABLE I.—*Total Oxalates in Soursob Leaves, June, 1934—In Intermittent Sunshine.*

1	2	3	4	5	6	7	8
Leaves Gathered.	Weight of Leaves Taken.	Total Dry Matter.	Total Oxalates.	Oxalate in Fresh Leaves.	Oxalate in Dry Matter.	Percentage Variation on Basis of Column 5.	Percentage Variation on Basis of Column 6.
	gm.	gm.	gm.	%	%	%	%
7 a.m. ...	25	2·0549	0·5875	2·35	28·60	—	—
5 p.m.....	25	2·3780	0·6025	2·41	25·30	+2·553	−11·54

The anlayses presented certain difficulties owing to the high water content of the plant and the extreme lightness of the foliage. Twenty-five grams, which was the amount taken in each case, represents a considerable volume of Soursob leaves, and a very large area of leaf surface. The presence of external moisture, such as dew, &c., in the early morning, adds very appreciably to the weight of the morning samples of leaves as compared with those gathered in the afternoon. This makes it difficult to weigh out equivalent amounts of the fresh leaves, and

introduces an experimental error, which was rather large in the first series of determinations undertaken. This is shown by the marked difference between the figures for the total dry matter in column 3, Table I. The increase in the total dry matter of the afternoon samples of leaves was probably due, almost entirely, to the greater amount of moisture adhering to the surfaces of the leaves gathered in the early morning. The same error accounts for the apparent increase in the oxalate content of the afternoon leaves (columns 4, 5, and 7). If the total oxalates are expressed, however, in terms of total dry matter, instead of the total weights of leaves taken, then the afternoon leaves show a slight decrease in acidity as compared with the morning ones (columns 6 and 8).

In the second series of determinations an attempt was made to obviate the experimental error in the first, by gathering the morning leaves at 9 a.m. instead of at 7 a.m. as previously. The dry matter of the afternoon samples was in this case slightly less than that of the morning leaves. If the percentage variation, either increase (+) or decrease (—), in the total oxalate content be expressed (1) in terms of the percentage of the total weight of leaves taken (column 5), and (2) on the basis of the percentage of dry matter (column 6), the resulting values are now in close agreement, whereas in the first determinations there was a marked discrepancy between them (columns 7 and 8, Tables I. and II.).

TABLE II.—*Total Oxalates in Sowrsob Leaves, August, 1934—In Continuous Sunshine.*

* Analysed after being kept in a dark chamber continuously for 48 hours.

These determinations are necessarily of a preliminary nature, and were not intended to yield more than a rough indication as to the nature and extent of any daily change in acidity that might be present. Obviously the subject requires to be investigated on a more ambitious and comprehensive scale before any general statements can be made concerning the diurnal variation in the acid content of *Oxalis cernua.*

Nevertheless, the results seem to indicate quite clearly that a reduction in the total oxalate content of the plant does occur during the day, and that this reduction is greater with increase in the duration and intensity of illumination. The plants analysed in June showed a reduction in total oxalate content of approximately one-tenth of the amount originally present after exposure to intermittent sunshine and cloud during one of the shortest days of the year. In August, when the days were noticeably longer, the acidity at the end of a bright sunny day was less by about one-third of that present at the commencement of the day.

Another sample of leaves, gathered in the afternoon, was kept in continuous darkness for 48 hours and then analysed, the results being given at the bottom of Table II. The total oxalate, in this case, was less by about one-quarter than that of leaves collected in the morning. This is in accordance with what might be expected. In succulent acid-forming plants, it has been shown that the rise in acidity during the night is dependent upon the exposure of the plants to light

during the preceding day. In the absence of such previous illumination, acid formation is interfered with, and this probably accounts for the results obtained in the case of *Oxalis cernua*.

It would seem, therefore, that there is, in *Oxalis cernua*, a type of acid metabolism similar to that which occurs in many desert succulent plants, and of which a diurnal periodicity is a well-marked feature.

The above observations suggest that Soursob is less poisonous by day than during the night, and it is conceivable that some practical use might be made of this. Any factors which tend to reduce the concentration of oxalic acid in the plants would naturally increase the margin of safety for stock grazing on Soursob pastures. It is at least possible that sheep, which have been rendered more susceptible to oxalic acid poisoning by a lowering of the calcium reserves of the body, as is often the case with ewes in lamb, might feed during the day with comparative safety on a Soursob pasture that would be dangerous at night. The fact that cases of Soursob poisoning are much more frequent in the early morning than at nightfall does at first sight suggest this view. On the other hand most Soursob fatalities occur during the early winter months, when the acid variation would not, presumably, be great, owing to dull weather and to the relative shortness of the days. Again, the greater amount of moisture in the herbage, the low temperatures, and heavy feeding during the night, favour the development of bloat and other troubles of a digestive nature, so that it seems doubtful whether the greater incidence of Soursob injury during the night is to be attributed to an increased oxalic acid content of the plants at that time, though it is possible that this may play some contributory part. The effect of an increased acidity would certainly be in the direction of reducing the margin of safety; and so, until we have more definite knowledge of the subject, it would do no harm, and might possibly do good, to keep stock off the Soursob during the night, in cases where this is conveniently possible.

IX. THE PROBLEM OF CONTROL AND ERADICATION.

Apart from the toxic effects due to the contained oxalic acid, Soursob owes its reputation as a weed to a number of circumstances, such as its wide distribution throughout the State, the great density of its infestations, the vigour of its growth and marked regenerative power when injured, and the efficiency of its method of propagation by means of bulbils.

Obviously we cannot expect to rid the State of so firmly established a weed as the Soursob by means of any simple magic formula. But it is possible to eradicate it from small holdings, and, in the case of the larger areas of agricultural land, much can be done to obviate the harmful effects of its growth. Fortunately there are certain peculiarities of the plant which make it less formidable as a weed than some others, such as Cape Tulip or Hoary Cress, which, though quite common enough, are not nearly as abundant as Soursob. Some of these peculiarities offer a means whereby the plants can, in certain circumstances, be eradicated or controlled.

In the first place, the thin texture of the foliage, and the general weakness of the aerial parts means that the plants can be attacked with chemical sprays of such dilution as would be quite ineffective in the case of weeds of coarser texture. A 2½ per cent. solution of sodium chlorate, which is about one-quarter of the strength required for Cape Tulip, will destroy Soursob plants, and can be used to control the weed in suburban gardens and other small areas. The weak solution does not kill the tougher grasses, &c., and the residual effect of the poison on the ground is almost negligible.

Owing to the cost, it is not practicable to use chemical sprays on large areas of agricultural land, but control can often be effected here by making use of another feature of the plant, namely, the limitation of its period of vegetative

growth to the winter and spring months of the year, and its dependence upon moisture. From the farmer's point of view the main difficulty with Soursob is its tendency to smother other plants, especially cereal crops during the early stages of their growth. This difficulty, however, is usually associated with mid-season sowing of crops, in which the early seedling growth is made to coincide in time with the most vigorous growth of Soursobs. By sowing early with a vigorous variety of wheat, or by the late sowing, after repeated cultivations, of an early-maturing variety, the trouble can, in large measure, be avoided. Such has been the experience at Roseworthy Agricultural College. The following account, which is taken from a joint report of College activities recently published in this *Journal* (July, 1934) by the Principal (Dr. A. R. Callaghan) and the Farm Superintendent (Mr. O. Bowden), well illustrates the principles involved:—

"Following 70 points of rain in mid-April, the sowing of the field 'Crouchs C' with the variety Ford was begun. The greater portion of this field was known to be badly infested with Soursobs. . . . . Germination was very rapid and satisfactory, the wheat grew rapidly, and at the outset gained a lead on the Soursobs. This ascendancy was maintained throughout, and in spite of the blanket of Soursobs which formed a dense undergrowth on the field, the wheat competed so successfully that the Soursobs, except for a few stray individuals, never flowered, and the wheat crop came through triumphantly, with a yield of 26bush. per acre off 56 acres, and nearly 3 tons of hay over the remainder.

"It is interesting . . . . to compare the treatments and results from two other fields where Soursobs were prevalent. 'Days C' was sown late, finishing on June 10th, to Waratah. Additional to the treatment given to 'Crouchs C' this field was cultivated, spring-tyned, and again cultivated, with the gratifying result that the Soursobs were absolutely subdued, and after the wheat had brairded only a few weak Soursobs were evident in the field, and their effect upon the resultant crop was negligible. From this field a yield of 26½bush. per acre was harvested off about 80 acres. Another paddock, 'Dalys C,' received intermediate treatment to those already cited, and was sown mid-season. This paddock was worked in April, at the same time as 'Crouchs C' was being sown, but was subsequently cultivated and spring-tyned just prior to seeding on May 17th to Ford wheat. Here both Soursobs and wheat came away simultaneously, and with weather conditions more conducive to Soursob growth than to wheat growth, the balance of competition was for some time largely in favour of the Soursobs. The crop was thinned out considerably, the yield as a result was considerably lower, at 20½bush. per acre, than those obtained as a result of the paddock treatments previously described."

From these results, and for the reasons given when discussing the morphology and vegetative life cycle of the plant, it seems that cultivation may do much towards controlling and possibly towards eradicating, Soursob, provided that it is undertaken at the right time. Theoretical considerations suggest that the most vulnerable stage in the life history of the plant is that at which the tubers have reached their maximum size, but before they have begun to contract; that is, when the energies of the parent bulb have been fully expended, but before the new bulb has begun to enlarge, and before the bulbils have reached an appreciable size. This stage probably occurs late in June, but doubtless depends largely upon the rainfall; in any case, more detailed information on this point is needed. Cultivation earlier than this would be followed by rapid regeneration of the plants, while later cultivation might mean the formation of some bulbils, and the withdrawal of certain bulb rudiments below reach of the farming implements.

Another method of control that has been suggested is to turn pigs or turkeys on to areas badly infested with Soursob, and, used in conjunction with cultivation, this would doubtless be a very effective means of control. The tubers are stated to be greatly relished by swine, which display great energy in rooting them out, and both the bulbs and the tubers have a considerable nutritive value. If a badly infested area is ploughed when the tubers are well developed, and if pigs are then turned on to the ploughed ground, it is probable that the area will be effectively cleaned of Soursob. The method is said to have been used with success at Gawler River and some other parts.

X. ACKNOWLEDGMENTS.

The writer is pleased to acknowledge his indebtedness to the following gentlemen for assistance in various ways in the course of the preparation of this paper:—

(1) The Librarian and assistant Staff of the Public Library, Adelaide, for much courtesy and help, and particularly for obtaining, on loan from the Public Library, Melbourne, Volume XXV. of the *Revue Général de Botanque* containing Ducellier's paper on *Oxalis cernua.*

(2) The Librarian, Public Library, Melbourne, for the loan of the work referred to.

(3) Mr. H. C. Trumble, M.Ag.Sc., Agronomist at the Waite Agricultural Research Institute, for permission to make use of some unpublished notes of his on the early history of *Oxalis cernua* in South Australia, and also for information concerning the control of Soursob by means of chemical sprays.

(4) His colleagues, Messrs. A. R. Hickinbotham, B.Sc., Dip.Ed., Chemist, and K. Woodroffe, R.D.A., Cadet in Chemistry, for the oxalate determinations described in the text.

Oats.

Mr. W. C. Johnston advises that he inspected a crop of New Zealand Cape Oats on the farm of Mr. F. H. Wolf, of Rosedale, which he reports as being suitable for seed.

PAPERS READ AT CONFERENCES.

CONFERENCE OF EYRE'S PENINSULA BRANCHES.
KYANCUTTA, September 9th.

RABBIT DESTRUCTION.

[L. H. DANIEL, Kyancutta.]

The presence of rabbits on his holding represents a loss to the farmer each year. The revenue, which is sometimes earned by the sale of skins and carcasses is more than offset by the amount of feed and crop they eat, the considerable time spent in keeping them in check, and the number of sheep they displace. Four or five rabbits can, on occasion, check the growth of an acre of crop. It is obvious, therefore, that rabbit destruction is a problem which must be attended to by every landholder whose land and adjoining roads are infested with the pest.

Unfortunately under present farming conditions, it is often impossible for a farmer to employ sufficient labour so that he can deal with the pest effectively. However, the following is the experience of the writer gained over a number of years:—

After harvest, when the rabbits are most numerous, every vestige of stubble and grass consistent with necessary feed should be burnt, and the poison cart should be used. Because of the rabbit's keen sense of smell the poison should not be touched by hand. Some oil of aniseed should always be added to the poison to make the smell of it attractive. The addition of sugar to the poison will also prove an inducement to them. Some success can also be obtained by ploughing in the warrens with a strong, single-furrow plough in the summer. The mouldboard should be removed to allow the plough to go to its maximum depth. Immediately after seeding, the extermination should be continued in earnest, for it is then they are breeding. Trapping is very effective if they have not assumed plague proportions. Spring traps are the best if only a few are about. Paper should not be used to set the traps, as it interferes with the action of the jaws and forms a pocket from which the rabbit's leg is easily pulled. Netting traps deal with rabbits more quickly if they are numerous. In either case, at least 40 traps are required. The netting traps should be constructed of 1in. mesh netting to prevent the escape of young rabbits. These traps require at least one bag wrapped right around them, two if necessary, and holes in which traps are not placed must be covered by bags and dirt put on the bags. It is usually a waste of time filling in the holes without this precaution.

FUMIGATION.

The hand-fumigators on the market are very effective for small to medium warrens, but plenty of fire and sulphur must be used. Another method that I have used is to mix a tin of phosphorous poison in four gallons of warm water, and pour this into a tin which can be corked up. A small quantity of this poured down each burrow as far as one can reach will create a gas which will kill the rabbits once the holes are filled in. The exhaust gases from a motor vehicle can also be utilised for fumigating by connecting the exhaust pipe to a burrow by means of a flexible metallic pipe. The engine should be speeded up to one-third throttle and the holes filled in as the gas appears. There is no need to add oil to the petrol. The gas will be quite visible and actually carbon-monoxide which is the destroying agent present in the gas, is invisible. The engine should be run for some minutes after all the holes are filled in. The engine oil must be changed at so many working hours in this case, and not at a certain mileage. About 2galls. of petrol will be used daily.

The system which the writer considers the best, consistent with time and expense, is to use a portable fumigator having three units, *i.e.*, engine, powerful blower, and a fire-proof furnace. Stumps are burnt in the furnace and plenty of sulphur is

thrown in at each warren. A large diameter flexible metallic pipe is needed to connect the furnace with the warren. This type of fumigator will force the gas to the rabbits no matter how deep they go, and a large area of country can be covered in a short time. Sulphur is obtainable at approximately 15s. per cwt. and 1 to 2cwts. per year will usually suffice even in extreme cases. After the burrows are fumigated they should be destroyed by ploughing in. This should be done before "outside" rabbits have had time to re-open the burrows.

Prevention is better than cure, and every farmer who can, should ring-net his farm. This will help to keep the pest in check, though it must not be thought that he is going to keep "the other man's rabbits" out entirely, even if they do not burrow under the netting, because the writer has seen young rabbits get through 1½in. mesh netting without much effort. It is hoped that in the near future the Government will pay more attention to the destruction of rabbits on railway property, particularly where the water mains follow the railway.

SIDELINES ON THE FARM.

[E. K. DYKE, Kyancutta.]

Since starting to write this paper things have altered quite considerably; there has been a considerable rise in the price of wheat, and there seems to be a tendency for wool prices to recede. In spite of this there are very few who will not agree that sheep are a necessity on the farm, not only on account of the wool and mutton they produce, but also because of the aid they are in keeping weeds down on the fallow.

There is another item to be considered, and that is the disposal of surplus sheep or lambs. In some years it is possible to have suitable lambs for export, but unless something can be done in the way of fodder conservation to help the lambing ewes in a season like the present, there seems little hope of making them a regular sideline. It is fairly easy to carry the rest of the flock over a bad spell if oats are grown and the grain stored, but this is hardly sufficient for forcing lambs along. It might be a good plan to make ensilage from part of the oat crop or from barley in the good years, and so have suitable feed for ewes in the drier seasons.

The ensilage could be stacked or put in one of the various forms of silo. On those farms that have the usual sandhills perhaps the best idea would be to scoop a deep trench through the top of one and fill that with ensilage.

Oats have proved quite a payable crop during the last year especially; they were readily saleable at about 4s. a bag for feed. Also, those who grew them had a very valuable feed reserve. Barley is not grown to any extent here, but if unable to grow a good enough sample for the maltsters it might be payable to feed it to pigs, especially if crushed.

Most farms keep a few pigs, and with a bacon factory at Port Lincoln it should be possible to make a little money from them. Several farmers in the district have procured the right type of pig, and seem pleased with the return from them. The best plan is to have small paddocks for them to run in, and sow these, if possible, in the winter with some quick-growing greenstuff. Almost anything in the way of greenstuff from the garden is readily consumed by pigs. They are very fond of pie-melons which are easily grown on fallow.

Cows can be quite an asset on the farm if properly cared for, but unless this is done they are more likely to become a liability. Ensilage is particularly valuable in keeping up milk production in the dry months of the year. A friend of mine who made ensilage last year, mostly from King Island Melilot, informed me that his cows kept up their production well during the summer with that fodder.

[*Papers Read at Conferences.*]

Fowls are a stand-by on most farms at some seasons of the year, and if more care were taken in the hatching of chickens at the right time results would be much better. Black Orpingtons seem to do very well on the farm, and from the results at the Parafield Competitions seemed to lay a greater proportion of their eggs during the cold months of the year than most other breeds. This is quite an advantage, as those are the months when eggs bring the highest price.

A small garden is another activity which should receive some consideration from those who have water laid on. A few fruit trees and vines can be kept going easily if some of the summer garden is planted between them. The water used on these plants will keep the trees going well. Several farms grow all their own vegetables, except perhaps potatoes. Onions do very well about here.

FALLOWING AND ITS SUBSEQUENT WORKING, IF ANY.

[J. DYKE, Kyancutta.]

Fallowing is necessary if only as an aid to better and cheaper production of wheat; an acre of good fallow is worth two acres of stubble ground, especially in seasons like the present. Also, the saving in seed and super is a consideration in the cutting down of costs of production. Fallowing should be commenced as soon after seeding as possible; in fact, immediately after if the plough or whatever implement to be used is in order. There are, of course, several methods which may be followed, and all have their good points, according to the class of soil to be worked and the district where situated. Where the soil is to be worked is of a sandy nature, the stump-jump tine cultivator gives good results, and enables the work to be done quickly. For classes of soil that pack solid with the traffic of stock feeding over them the plough is preferable to the cultivator, for the latter is apt to get strained if a lot of draught has to be used. Regarding depth of ploughing, 2in. is deep enough on the average, but that again depends upon the class of soil. After the plough is finished the harrows should be used, preferably across the ploughing, which will break it down, pack the subsurface, drag out any loose stumps the plough may have partly buried, and help to kill more of the small weeds which will have germinated. After this has been done the fallow can be left for a while until the weeds show up, when sheep should be turned on to deal with them and to help pack down the soil.

Any further cultivation needed could be done with harrows to which share points have been attached; these will cut all the weeds, only cultivate to a shallow depth, and not fetch up a fresh supply of weed seeds to germinate, which the cultivator is likely to do.

HARROWS.

[O. J. MURPHY, Warramboo.]

"Harrow" is a very old word. It occurs in the Old Testament. As a noun it referred probably to a threshing machine. The verb rendered "to harrow" occurs also in the Old Testament, and expresses apparently the breaking of clods, though it is doubtful whether this was done by any machine such as we call a harrow. Nevertheless, the harrow is one of the oldest of agricultural machines. Many types and designs have been devised to meet varying needs, and to-day no farm equipment in South Australia is complete without a set of harrows.

Primarily the harrow was used to break down clods, and on the heavier soils of this State harrows are still used for that purpose. A common practice is to use harrows immediately after the plough during fallowing operations, particularly on heavy clay soils to break down clods, scatter the weeds, and to provide a smoother surface for subsequent tillage by the cultivator.

[*Papers Read at Conferences.*]

The two main types of harrows which concern wheatgrowers are the set or plain land harrows, and the stump-jump harrows for used on stumpy or stony ground. Each kind of harrow is obtainable with plain spikes or with share points. The latter type are usually referred to as "scarifier" harrows.

Harrows are used not only to break down heavy soils, but also to destroy weeds in the early stages of growth, and considerable importance is attached to the arrangement of the teeth or spikes of the harrow in order that each spike may do the maximum amount of work so far as the destruction of weed growth is concerned.

Another important feature of the harrow is its effectiveness in the production of a good seedbed—a fine, shallow mulch over a well-compacted under layer. The use of harrows in this direction is especially valuable during the period between harvest and seeding time.

In regard to the use of harrows in this district—where considerable areas of the soil are of a sandy nature liable to drift—it may be said that harrows are not necessary to break down the soil. Their use is confined more to the destruction of weeds and to the production of a shallow seedbed. It is sometimes contended that the use of harrows causes drift, and this contention has caused an aversion from the more general use of the harrow.

The opinion of the writer formed during a period of five years in this district is that the harrow used intelligently is a very effective machine. It is a comparatively cheap implement, easy and inexpensive to keep in good order. Over 90 per cent. of our fallowing and seeding operations during the past five seasons have been done with a rigid-tine cultivator, a disc drill, and a set of harrows. We have used a combine also, but have found the disc drill and harrows equally effective, less expensive, and quicker than the combine. Although we have not used harrows extensively on fallowed land prior to harvest time, we have found during the past two seasons, when there was an abundant growth of grass, that the use of harrows immediately after the first fallowing operation by the cultivator enabled us to make a much better job of the subsequent cultivation of the fallow in the spring time.

In regard to drift, our experience is that summer rains—particularly heavy showers during thunderstorms which have a smoothing action on fallowed ground—are the chief cause of drift. Harrows used after such rains, rather than cause drift, have a very marked effect in checking the shifting of the soil. It is suggested that harrows be used freely after rain in the late summer and autumn. In addition to checking any tendency of the soil to drift the growth of weeds is checked, and the soil is left in excellent condition for sowing with the ordinary disc drill if so desired.

It is more than probable that the intelligent use of harrows in autumn will give better crop results than allowing the fallowed land to remain untouched until seeding, and then attempting to sow the land and destroy weeds with one stroke of a combine.

During the past two seasons a patent share which can be clamped to the spikes of the ordinary harrow has been on the market. Harrows with these shares attached are practically converted to scarifier harrows, and are very effective in the destruction of weeds in their early stages of growth. The ridges in the soil left by these harrows are obviously more pronounced than the "track" of the ordinary harrow, and therefore more effective as a check on drift.

The writer contends that harrows in conjunction with the disc drill form a better combination for seeding purposes in this district than the combine, particularly on the newly-farmer areas, where the presence of stumps is bound to cause the breaking or straining of the tines of the latter machine, loss of time due to stumps lodging between the tines, and expensive repairs, which result in an unsatisfactory job.

[*Papers Read at Conferences.*]

HORSE BREEDING.

[M. F. O'Brien, Kyancutta.]

At the present time well-bred horses are bringing good prices, due, no doubt, to the curtailment of breeding a few years ago when tractors were taking the place of horses on so many farms. A large number of farmers who were previously using tractors have now turned their attention to breeding horses, as breeding is the most economical way of obtaining a really good team. Most farmers are breeding one or two foals each year to replace aged horses on their farms, while others are breeding more than they require, and these surplus horses will be placed on the market during the next few years, with the result that prices will not be maintained at their present level. It will therefore be necessary for those who are breeding horses for sale to pay special attention to the type of horse that they are breeding. A good type of farm horse will always command a fair price, while inferior and medium types will be hard to dispose of.

After selecting the best mares on the farm, be very careful in the choice of a sire. Do not breed from a horse not true to type. Many farmers breed from any sort of a colt because they can turn him in the paddock with the mares and save the trouble of looking after an entire. This method is false economy, for it costs no more to rear a good type of foal than a half-breed. It may be said that the half-breed will work as well as a good horse, but he will never look as well in the team, and it should be every farmer's desire to have as good a team as possible. Again, the medium horse will never command near the price that a good type horse will in the sale ring.

The farmer who does not keep an entire, and who patronises a travelling horse should, if he has a choice, look well into the merits of each horse travelling in his district. If you have thick-set, nuggety mare always choose a good, tall horse, and *vice versa,* but remember he must be true to type, and a proved foal-getter. I prefer the Clydesdale type of horse for farm work. They usually prove to be good workers, combining strength with pace, and are exceptionally good tempered while the mares are always good mothers.

Care of the Foal.

When the foal is born catch it and paint the navel with iodine, repeating the treatment daily for three or four days or until the navel has dried up; this will often prevent navel ill. Also, see that the mare is normal and has plenty of milk. Give her a hot bran mash after foaling, continue to give liberal quantities of bran and crushed oats if she does not appear to have sufficient milk for the foal, and allow her to graze at will in a small paddock of greenfeed. Should the foal refuse or be unable to suckle it may be necessary to give an enema, but before doing so try working a little olive oil into the anus with a finger. This often gives relief to the foal and saves straining.

To wean a foal I prefer a small paddock of greenfeed. A small quantity of chaff and oats may be made available, the foal having free access to plenty of clean water. The mare must not be forgotten, and the day the foal is weaned the mother should be fed on chaff (no oats) containing 1lb. of Epsom salts, and be given only small quantities of water for a day or two. It is best to keep the mare working as this will help to dry her off. Should the udder become swollen and hard rub first with olive oil, then with vinegar (three parts) and olive oil (one part), and if not working give plenty of exercise. Breed foals early, say, in July or August. At this time of the year there is usually plenty of greenfeed for the mares, and the foals when older will shed their coats earlier, and usually look better than a late foal. To breed early foals and wean them at, say, six months it is essential that a small paddock of lucerne be available.

[*Papers Read at Conferences.*]

Colt foals should be castrated in spring at about 14 months. It is best to obtain the services of a veterinary surgeon, if one is available, but the operation may be successfully performed by any competent stockman. The three main points to remember are:—First, see that the emasculators have been sterilised; second, rope the colt securely and throw him on a patch of green grass—not in the stable or yard where there is any sign of stable manure; and third, use plenty of disinfectant.

The colt or filly can be broken in at two years by giving it a few short yokes in the cultivator or harrows when working back the fallow. This should harden the shoulders, and if worked during the harvest they will not be so likely to scald. Do not work a two-year-old more than four or five hours a day in a stripper or harvester if the weather is very hot.

It is advisable to put them in a waggon when wheat carting to teach them to pull, but do not overload, and do not expect a horse to do a full day's work or pull his full share of a load until he is at least three years old. If you treat a horse well while it is young you will be amply repaid by the extra service it will give when it is older.

TREES FOR SHADE OR SHELTER.

[Frank Chilman, Warramboo.]

Of all the various form of gardening activity, the growing of shade and ornamental trees and shrubs gives the most lasting pleasure and benefit, and in the long run gives the best returns for the amount of labour and expense involved.

In a district such as ours there are not many beautiful native trees, and very few homes can be built among handsome natural trees, so that it becomes necessary to grow trees for shade and shelter as well as to beautify our holdings. The various kinds of gums seem to be the best suited for this district, particularly the Sugar and Tooart, both being very hardy and quick growing, and can easily be raised from seed. The only expense is the 6d. for seeds, one packet being enough for several years. Ants seem very partial to these seeds, and it is just as well to try and protect them from these pests until the plants are well above ground.

Pepper trees, too, are a good standby, doing particularly well in sandy soil, and making a wonderful shade and shelter. They are easily raised from seed, but need transplanting very young if sown in a tin together. The Tagasaste or Tree Lucerne is a nice, ornamental, flowering tree, grows quickly with a nice graceful foliage, and has a mass of flowers in the spring. It makes a good break of shelter.

The various pines such as Insignis and Aleppo make nice trees, but are very slow growing. I have not been successful with pines of any description. Sometimes the native pines can be dug up when small and transplanted around homesteads, and eventually grow into nice trees. There are a number of other trees such as the Kurrajong, Tamarisk, Moreton Bay Fig, &c. It must be remembered when planting trees of any description that they are robbers of soil, and you cannot expect to grow anything else close to them; pick the place and plant them for shade and shelter as well as to beautify the homestead.

PAST AND PRESENT-DAY FARMING ON THE WEST COAST OF SOUTH AUSTRALIA.

[A. E. PLACE, Palabie.]

The methods adopted by farmers prior to the introduction of drills and fertilisers were, after getting the scrub down—which had to be cut with an axe—to plough the soil, always broadcasting the seed; some farmers sowing before ploughing, others after ploughing, then using the harrows to cover the seed. As much as 15bush. to the acre have been reaped from ground cultivated in this manner. When superphosphate and the drill appeared on the scene they caused a great diversity of opinion, many farmers declaring the soils in these parts heavy enough for wheatgrowing without super, some declaring that with the limited rainfall the super would cause the crops to blight or burn off during September and October, which months were very frequently dry. Many of the farmers around Murat and Denial Bays had migrated from Yorke Peninsula prior to the advent of super, and on reading of results obtained from land on which they had been practically starved decided to use the fertiliser from which a very marked yield was obtained, and within two years every farmer was using super. These farmers always used the plough on new ground, and in many instances gave the ground a light ploughing the second and third years, cultivators at that time not being up to the standard of the present day.

During the period from 1927 to the present time farmers on this part of the Peninsula—from Poochera down the line and north to Cootra, and in this and adjoining districts—seem to cling to the idea of just drilling in new ground, sometimes even to the second and third year This method instead of giving maximum results invariably produces the opposite. In giving preference to the plough I do so with the contention that it gives a more uniform seedbed, which is a big factor in producing wheat; also it breaks more roots, thus considerably retarding the growth of shoots, this being very beneficial to the crop. By the surface roots being broken the crop receives more moisture when coming to maturity.

By putting the work into new ground more successful results will be obtained, and farmers, instead of looking for a cheap crop the first year, have a much better and more reasonable chance of getting that result the second year, as they have less shoots to contend with, and with better cultivation get a more prolific growth, thus ensuring a better burn of stubble, which will again bring the mallee menace to a minimum. There is no doubt live stumps are a menace to production, and the sooner this menace is eradicated the sooner is a profit instead of continual loss going to be the lot of the farmer.

[*Papers Read at Conferences.*]

PINNAROO LINE CONFERENCE, September 18th, 1934.

A FEW AILMENTS COMMON TO SHEEP IN THE MALLEE.

[R. A. JENKINS, Lameroo.]

Pink-eye.—Symptoms—Running at the eyes and staggering walk owing to partial blindness. Isolate as soon as noticed. I have always found boracic powder an effective treatment. Carry the powder in a bottle in the waistcoat pocket, also a few sheets of writing paper if there are many patients. Make a tube about ¼in. in diameter, and blow a little powder into the eyes while holding the lids open with the fingers.

Scabby Mouth.—Cases of this trouble have been brought into the district, especially from the Lakes district and Lower South-East. Isolate and swab with a 1 per cent. solution of bluestone. Keep in a paddock of long feed if possible.

Foot-rot has been noticed at Lameroo in wet seasons. The hoofs should be kept trimmed at all times in sandy and soft country.

Nasal-bot is very prevalent in this district. If a sheep's nose is running profusely and it is continually blowing its nose, it is usually an indication of nasal-bot. Sit the sheep up and run a weak solution of kerosene and soap suds into the nostril. This will make the bot release its hold, and the sheep will blow it out, and it can be destroyed.

Bottle Jaw.—This complaint has been observed in the Mallee. It is a distinct swelling under and between the bottom jaws. If inspecting a flock of sheep with the idea of purchasing, and this characteristic is observed, do not confound it with dew-lap. Do not buy them; it is a sign that they have come off unhealthy country, and are no doubt infested with worms and liver fluke. On examination of the eyes and skin a general anaemic condition will be noticed. If this trouble develops in a flock starve for at least 12 hours, and give one Cooper's tablet to two-tooths and two tablets to grown sheep. Repeat the dose in a fortnight. Always keep a lick of one part super to three parts coarse salt available for the sheep.

Infectious Toxaemia.—This disease is widespread in the Mallee and in other parts of the State. Most farmers are acquainted with the symptoms—staggering gait, weakness, and knuckling over at the knees. Any aged sheep appear to take the complaint, and from observation it seems to be no respecter of sex. Death nearly always follows an attack, which usually lasts only a short time. A *post mortem* shows the paunch and small intestines to be full of gas, and an abnormal quantity of fluid in the heart sac, lung cavities, &c. The kidneys and fat have a watery appearance. Undoubtedly this complaint has caused the death of thousands of sheep in the Mallee, a great many of which could have been saved with the use of a little more discretion and observation. Read the bulletins published by the Council for Scientific and Industrial Research.

Entero-toxaemia.—This disease is caused by a germ which remains in the soil for an indefinite term, and asserts itself under favourable conditions. It has been found that flocks depastured on germ-infested land for a number of years become almost immune, which fact tends to signify that it is advisable to keep up flock strength by breeding rather than by purchase. Methods of Control—A vaccine has been formulated to inoculate against the disease, but is not available commercially. The trouble comes in nearly all cases in sheep which are doing well and running in luxuriant feed. This would signify a possible lack of roughage which all ruminants require, and also lack of exercise. Therefore, move the sheep into a paddock where they have to work a little harder for their food. It is essential—if it is desired to keep this disease in check—to completely incinerate all carcasses of sheep and other animals on the property. In any case this should be done to check blowflies.

[Papers Read at Conferences.]

Pulpy Kidney in *Lam*[illegible] itself in sucking lambs of all ages, especially in the mutton breeds running on rich clover pasture. Treatment, unfortunately, tends to defeat the object of the lamb raiser, because should the trouble become too prevalent it is essential to remove the flock on to rough pasture if one does not wish to lose a large percentage of lambs. I have successfully treated a number of apparent cases of this complaint by drenching with turpentine, 10 to 15 drops, and 2 dessertspoons of raw linseed oil well shaken. A sheep is easy to drench if a small olive oil bottle is used. Do not hold the head too high. Farmers should make more *post mortems* of their animals, as by doing so and making observations they will notice many conditions which should be of an educational value.

THE APPLICATION OF LOCALLY PRODUCED FUEL IN REDUCING TRACTOR FARMING COSTS.

[E. V. HAMMATT, Lameroo.]

The necessity of being able to equip mechanically propelled vehicles to operate on other than liquid fuels has for a long time been realised by the farming community, and it is keenly appreciated that the scope of the tractor and truck would be considerably increased were it possible for them to use locally produced fuel.

Many inventors during the last few years have exerted their talents and energy towards this end, and as a result many machines have been produced that are giving more or less successful results. Notwithstanding this fact, the writer was not deterred in his attempt to evolve something apart from the orthodox, and to claim in the plant which is the subject of this paper results far in excess of all others yet demonstrated.

PRODUCER GAS.

The most satisfactory solution to this appears to be the use of producer gas—the second cheapest and best of all artificial fuel gases used in internal combustion engines. The general adoption of this class of power would result in a very large reduction of tractor farming costs. Furthermore, it would retain thousands of pounds in the State that are sent out of it for liquid fuel, and materially assist in providing employment for a number of men in preparing fuel for use in gas producers.

My plant has been working on a tractor on my farm for the last 20 months continually, and the tractor works very efficiently on gas, doing all that is asked of it in the same way as if it were running on liquid fuel. This was obtained mainly be certain alterations to pistons to obtain higher compression. The plant itself is attached firmly to the tractor and is so light—only weighing 6cwts.—that it does not upset the balance of the tractor; actually, it can be so placed as to compensate any inefficient draw-bar loss.

Charcoal costs 1s. per bag, therefore the purchase of petrol and oil are the only additional fuel outlay. A remarkable saving in engine oil is effected by changing once in 200 hours instead of every 50. With liquid fuel there is definitely no crankcase dilution, the oil getting thicker instead of thinning out. Longer engine life is obtained and less overhauls are necessary running on cooled charcoal gas than on oil of high volatility. The gas producer comprises a generator fitted with a hopper carrying enough charcoal for approximately 4 hours running without stopping motor, a recharge which only takes a few minutes. The gas is cooled and filtered through scrubbers, and cleaned before it passes to the mixer where it is mixed with air ready for combustion in the tractor engine.

The producer uses 1½galls. of water an hour, and the tank capacity lasts as long as the charcoal in the hopper. Petrol is used for starting the engine and to create a suction to draw the gas through the scrubbers. It requires 1½ to 2 pints of petrol for starting from cold, which takes about 10 minutes.

[*Papers Read at Conferences.*]

Operating a gas plant is very simple—the air supply to the mixer and water drip to the generator are the only operations needed, for when once moving under full power it runs consistently and requires no adjusting.

COSTS.

The following are the working expenses for a caterpillar tractor worked on my farm both with liquid fuel and producer gas:—

Pulling 20 Sun Combine Drill.—400 *Acres.*

Liquid Fuel.	£	s.	d.	Gas.	£	s.	d.
185galls. kerosene at 1s. 0½d. ..	9	12	8	50½ bags charcoal at 1s.	2	10	6
15galls. petrol at 1s. 7d. ..	1	3	9	11galls. petrol at 1s. 7d.	0	17	5
12galls. B. oil at 5s. 6d. ..	3	6	0	4galls. B.B. oil at 5s. 6d. ..	1	2	0
	£14	2	5		£4	9	11

Pulling 8-Furrow Heavy Fallowing Plough.—550 *Acres.*

Liquid Fuel.	£	s.	d.	Gas.	£	s.	d.
440galls. kerosene at 1s. 0½d. ..	22	18	4	145 bags charcoal at 1s.	7	5	0
30galls. petrol at 1s. 7d. ..	2	7	6	20galls. petrol at 1s. 7d. ...	1	11	8
24galls. B. oil at 5s. 6d. ..	6	12	0	8galls. B.B. oil at 5s. 6d. .	2	4	0
	£31	17	10		£11	0	8

Pulling 10/ft. Royal Header.—440 *Acres.*

Liquid Fuel.	£	s.	d.	Gas.	£	s.	d.
210galls. kerosene at 1s. 0½d. ..	10	18	9	105 bags charcoal at 1s.	5	5	0
18galls. petrol at 1s. 7d. ..	1	8	6	13galls. petrol at 1s. 7d. ...	1	0	7
12galls. B. oil at 5s. 6d. ..	3	6	0	4galls. B.B. oil at 5s. 6d. .	1	2	0
	£15	13	3		£7	7	7
Grand total for 1,390 acres	£61	13	6		£22	18	2

BREEDING AND FEEDING PIGS FOR MARKET.

[E. A. DAVIS, Pinnaroo.]

Owing to the possible trade with Great Britain by exporting pig products, it behoves every farmer to seriously consider turning portion of his grain into pork and bacon, thus returning a more payable price for grain, reducing the huge surplus that there is in the world at the present time, and bringing about a big saving in cornsacks. The grain used for the purpose of feeding to pigs can be put into secondhand bags for two or three years, or in super bags that have been washed and cared for in such a manner as to make them safe for further use. We need not reckon on saving only wheat, because barley and oats are excellent feeds, barley being the best of the three, while the other two cereals play their part.

Barley can be grown profitably; it can be sown before or after wheat. If sown before quite a lot of grazing can be obtained from it, and if not grazed too long will yield a good return. On the other hand, it can be sown late, which is considered to be the best time to sow if high yields are required. This is a matter of seasonable conditions. Oats, too, can be grown profitably and easily if only grain is required. Assuming that the grain is available it is as well, before obtaining any number of pigs, to make the necessary yards and pens, always allowing for and keeping in mind room for expansion.

HOUSING.

Sties are not necessary to any great extent; they are only required for farrowing or finishing for market; the sow only needs the use of a sty for three weeks, and pigs that are being finished about the same time. Sties can be erected easily with a few mallee forks and rails to form the skeleton for a straw roof. Straw is

warmer in winter and cooler in summer than iron. An excellent floor can be made from old railway sleepers laid the reverse side up to what they previously have been, and placed about 1in. apart, giving the floor a very gentle slope to provide drainage. They can be grouted in with cement to prevent them from collecting refuse and making it impossible for the pigs to root up the floor.

Four pens measuring 8ft. x 12ft. will be sufficient for 6 or 8 sows; one sleeper will cover approximately 6 square feet, which means that 16 are required for 1 pen. These can be obtained locally for about 1s. or 1s. 6d., plus 1 bag of cement at 8s. 6d., making the cost of 1 pen between 24s. 6d. and 32s. 6d. This is very cheap, and will last a lifetime.

Make the grazing paddock secure by placing 3 barbed wires around the boundary about 4in. apart, and strain tightly. If this is done ordinary fowl netting will hold most pigs. For shelter straw stacks are best. Pigs are clean if kept clean; they will always choose and keep one corner of their sty as a privy, which should be cleaned out every second day at least, and the bedding not allowed to become wet, or dry, or dusty; throw out and renew as it is required. Give the floors a wash once a week—not only do the pigs appreciate it, but it keeps down the smell so often noticed where pigs are kept. The pigs, too, will enjoy the hose being turned on them, but see that this is not done in the evening or they may catch cold.

Sire and Dam.

Having decided to keep pigs as a sideline, it is essential to immediately fix on the type and class of pig that brings the highest price at the market, and which is most sought after by butchers and curers. Examine which pays best, to feed for export or local market. Having made a decision, rigidly adhere to it.

Before good pigs of any breed can be produced it is first necessary to have a good mother and a good sire. When these are available it will be possible to raise twice as many pigs, and each pig will be worth twice as much as animals obtained from a poor mother and a poor sire. Remember, a poor pig eats more than a good one. Pigs that will grow rapidly and large, and make the most pork out of their feed, cannot be raised unless the mothers and sires are from pig families that produced big, thrifty pigs. Breeding counts in pigs just as it does in any other stock. The brood sows must raise as many good pigs as they can—that is what they are kept for. If the foundation sows are not the very best, and the very best cannot be procured, select the best available and use a good sire, and from the litters select the best sows each year.

No matter how much good feed is fed to pigs, no matter how well sheltered and free from disease they may be, they will not make the best job of converting feed into pork or bacon unless they have the right kind of breeding. Let farmers not fool themselves that any kind of pig will do—a good sire is essential. Sometimes there may be an excuse for using a nondescript sow for a breeder if it is not possible to obtain a better one, but there is no excuse for using an inferior sire. There are good sires within reach of all, and it is a money-losing mistake to use anything but the best sire. The way to improve common stock is by using good sires.

Type of Pig.

The pig needed for present-day requirements is one with a long body, lean, fine shoulders, and light in the jowl; but not too leggy, with plenty of chest room, with the bulk of weight behind the shoulders and side, becoming deeper towards the hindquarters. If suckers are to be bred—which is the cheapest way to get them—select a sow from a litter whose ancestors have been big producers and quick growers, possessing a strong constitution. From the litter choose the biggest and best pig, provided that it is of good type and conformation, and with an active appearance. Sows should not have less than 12 teats evenly spaced and placed as near to the fore legs as possible. It is important that the teats should be of an

even size—small teats are usually blind. Having selected the sow, give her plenty of run; do not cramp her in a small sty. A grass paddock is preferred in which is provided a self-feeder with minerals added.

At the age of from 8 to 9 months mating should take place to a selected boar. Obtain the service of a sire that has been selected on the performance of its sire and dam by years of very drastic culling, and who possess a record to back up their ability to produce quick growing, early maturing pigs of a uniform size. In each case the pig selected should be a pure-bred animal. The sow, too, should be pure in this respect, although it may be a cross its parents should be pure bred, possessing the same record as the boar.

Farrowing.

Both sow and boar should be handled as much as possible, and with every care not to knock them about, or this will surely bring trouble from the sow at farrowing, and the boar will become a nuisance if he is vicious.

Having mated the sow she should have every care and plenty of good feed to keep her in good heart, but do not feed to fatten; all that is required is good, solid condition. About a fortnight prior to farrowing she should be brought into a pen and fed on sloppy food, with a dose or two of Epsom salts. This should be done twice before she farrows. At farrowing it is as well to be at hand to remove the young pigs from the sow, dry them with a dry bag or cloth, and put them in a box with a little fine straw, fix the box high up in the sty so that the sow cannot get to them. Be particular that there are no draughts. After the sow has finished farrow put the young pigs to the teats and allow them to have a good feed. If it is night take them away for the night, thus allowing the sow to rest undisturbed until morning. It must be remembered that this litter is the means of profit or loss on the preparatory feed that has been given to the sow. Therefore, it is well to give her 3 or 4 days' attention by taking the pigs away after every drink—about every 2 hours—until 10 at night; then take them away for the night. Continue this practice for a week, by which time the little pigs are able to care for themselves.

The loss of young pigs is something of very great importance. Suppose it costs £4 per year to feed each sow. If she only rears 2 pigs, each pig has cost £2 the day it is born—very high-priced pigs. If she raises 4 pigs, each one costs £1—not much chance of a profit. If she raises 2 litters of 10, the first cost is very reasonable. Therefore, do not neglect the sows at farrowing. A week spent this way and doing odd jobs in between is the best pay a man will receive for any week that he works on his farm in the year. When one sees a sow with 2 pigs for which she has been fed 4 months the sow is blamed; often it is not the sow but that man who is at fault.

Raising the Litter.

The litter must be given proper attention, first by feeding the sow well while she is suckling, but do not rush the feed, continue to feed her as she was fed before farrowing, gradually increasing as the pigs grow. Do not change her diet; this will affect the young pigs, and probably cause scours at about a month old. Should this occur, give each pig 1 teaspoon of castor oil, and if this fails repeat the dose. This trouble is usually caused by change of diet, dirty floors, or the sow lying in a filthy sty and the young pig shaving to suck it off when drinking. This also infests them with worms. At 3 weeks of age the young pigs will start to eat. They should have a shallow trough with a little milk placed where the sow cannot get at it. This will relieve the sow, as they will not need so much from her. From this stage the sow and young pigs should be on pasture with a shelter provided. The young pigs should have access to the self-feeder. This can be kept away from the sow by means of a creep—a small pen with the opening just too small for the sow to get through. After 10 weeks the sow should be taken away from the young pigs and mated during that week to the boar.

These pigs should now be kept going with minerals added to their feed, together with crushed grain and meat meal at the rate of 4½lbs. per 100lbs. grain or ¼lb. of meal per day per pig and skim milk if available. Meat meal should always be fed to pigs; it supplies protein which quickens the growth, and the pigs are sold earlier, which means greater profit. Supposing the average pig was sold at 6 months it would cost approximately 3s. 4d. per head for meat meal. To sell them at from 5 to 5½ months means a saving in feed, and while the cost is slight it means a saving of 1s. per head, and if 10 are reared, 10s. on the litter besides grain.

Worms and Lice.

Worms can be effectively treated in many ways. One of the best is the use of turpentine. They can also be treated with worm capsules which are given to each pig individually at a cost of under £1 per hundred; only 1 is necessary for each pig. Pigs should be dosed at weaning time; it is not recommended before. Keep a lookout for lice. No pig will thrive if these pests are allowed to suck their blood. Old sump oil will stop this pest.

Topping Up.

Assuming that the pigs are nearly ready for market, bring them into a sty and top them off with grain. It will take about a fortnight to complete this. Supply good bedding and keep them clean; do not think that they can be hurried away; much money is lost by pigs not being finished, and there is as much lost by overdoing them. Their condition should be sleek, with a firm fat over the backbone just sufficient to avoid the bone from being felt easily. The skin must be soft, and the hair glossy. Do not allow the pigs to be hit, or bitten by dogs, which lowers their value.

No matter how good the feed do not lose sight of the fact that profits come from the number reared per sow per litter. It does not seem much when a little dead pig is thrown over the sty wall, but do not forget that represents about 100lbs. that the sow has eaten. Many thousands of young pigs are lost through neglect. If pigs are worth keeping they are worth the same attention as horses, cattle, or sheep.

SOME FACTS THAT WILL HAVE TO BE FACED DURING THE NEXT YEAR.

[W. J. Morcom, Lameroo.]

There will be many problems to face during the next 12 months, for as seasonal conditions this year do not give promise of a big harvest, the farmer will have to plan well ahead and work accordingly, so that he may be able to carry on and keep his stock, &c., in working order. This year there are many farmers who are not fallowing; they say that they will be putting in the same land again next year. That is a mistake, and even in a year like this it is essential to fallow, for by having fallow reasonably clean should next year open early with a good rain some quick-growing variety of wheat could be sown early, even in April, and that by July would probably give an abundance of good greenfeed, which could be fed off even by working horses next fallowing time, for hay stacks will not be too plentiful this year.

Some also say that they cannot fallow, for if they do they will not have any feed for their sheep. So far as that is concerned, all the feed the sheep are getting from a lot of paddocks that could be fallowed is very small, in fact, some land that was fallowed early has almost as much feed on it as that which was not fallowed.

There is another point that must not be overlooked when harvest time comes; we will have to bind the best of our wheat crops for hay, otherwise there will be a lot of hungry horses about next year, and it will pay to bind some of it a little

on the ripe side, then if needs be some of it could be headed or threshed and chaffed with good hay, and it will make good feed. Any straw will have to be cut also, for it is much better to cut it than to be raking it up later on. These jobs mean a lot of work, but they will have to be done.

It will also be a good plan to sow a portion of the stubble land, especially the sandiest portion, with rye, because that will grow quickly and provide pasture for sheep. Of course, I mean by that if the season is normal so that these things will grow, but we must make provision and do our part if we are going to maintain our stock on the farm. A farm without stock is a very poor advertisement, but it will pay to get rid of all old sheep if possible and rely more on the younger sheep as they can stand more hardships than old ones.

There is also the cocky chaff from harvesters and headers; it will pay handsomely to save all we can of this, for young horses and cattle will do well on it—especially if a little hay chaff and molasses are mixed with it—much better than running out licking up sand which causes a lot of trouble.

We can also make a saving as far as our haystacks are concerned by using more corn and less chaff. In normal times we do not notice this so much, but now it is necessary to be careful. Horses being fed in the paddock at midday from nosebags can—with ¾ of a kerosene tin of chaff and ½gall. of crushed oats and wheat mixed—have quite a good feed in three-quarters of an hour, and are ready for work, and can be unyoked earlier in the evening. If horses are given a fair corn allowance they will be hardier and work more satisfactorily. A good lick for horses is salt and super (50-50) mixed with molasses. They are very fond of it, and it helps to keep them healthy, stops them from rubbing down the fences and eating manure that is lying about the yard.

In conclusion, may I say I have only quoted these facts from the way the season is now? Should we get a wet spring things may be different, but we must face the facts as they present themselves to-day and be ready for any emergency that may arise.

WHAT OF THE FARMER OF TO-MORROW?

[M. S. Davis, Parilla Well.]

Our State being mainly devoted to primary production, we hear the cry "the farmer is the backbone of the country," and concern is shown at the desire of men and women to leave the land for the comforts and privileges of cities.

Compare circumstances and existence under each heading—city *v.* country—the city folk have education, regular hours, home conveniences, social, religious, and sporting advantages, and at least a living wage equivalent to the amount of work done. Compared with the country—isolation, educational limits, burden of debt, hours of work extending from daylight to dark, lack of home conveniences and necessities, and a limited outlook and status.

The question may be asked, "Why do men stay on the land when their lot is so hard, and why is it that some people on the land seem to know nothing of the disadvantages stated above?" The country is not concerned about these types of people, for some have inherited properties free of encumbrance, or have secured a cheap property and have had good seasons, or selected land years ago and have been rewarded by thrift. Others remain on the land because it is part of them or seems to be in their blood, and so they struggle on against adverse circumstances, environment, and conditions, hoping that their children may have it easier, and to-day the majority are in these circumstances, and their children are the ones that are going to be to-morrow's farmers if we can hold them, and how to do it is to-day's problem.

What has brought about this condition—bad seasons, low prices, and interest. The farmer's son is brought up under the gospel of "get rich quick and retire"; he is told of the wonderful crops grown on new land or stubble or ploughed-up

[Papers Read at Conferences.]

land put in when seasons were good and wet; rarely do we hear of the wonderful results obtained from a perfect piece of fallow in a dry year, and we have developed into cropping for wet years irrespective of lean times coming, and have allowed stock and plant to get too big and overhead expenses become so heavy that we have found ourselves at a loss. Those in authority have been just as much to blame; it is either, grow more wheat, keep more sheep, profit in cows, or feed corn to pigs and poultry, until we find the farmer chopping and changing from one to the other, paying high prices, and just being established in one branch when it is becoming glutted, and very often we see the press booming someone who is doing well at some particular sideline, and crowns it by saying the farmer could not make it pay if he had to pay wages to employed labour, but his family do the work and show a profit.

That parent is foolish, for any son or daughter on the farm is worth infinitely more than any hired servant, and should he or she work for less? Why will not the boys stay on the farm? Because they work for nothing until they want to get married, and then try and start on their own with a young wife and growing family, and all they know is how to work, to say nothing of the expense and management of a property, because father has done all that!

Consider this question with a balanced mind and it will be seen how serious the position is and how vital it is to the maintaining of our status as citizens of equal rights with those under other circumstances. The farmer's son attends the local country public school, and at the age of 14 is ready to leave and at the same time the parent would like to give him extra education, but cannot afford to because the son can drive the plough and save a man's wages and keep.

He will prove the best man that ever worked for the farmer, and if helped and given hints he will be a better man than his father, and when all is said and done that is what a parent wants—for his son to be the best farmer in the district.

Now consider his education to attain this end, other than being a Bureau member. The boy after leaving school is bound to become very keen on his job, and may become so engrossed in his work that he is liable to lack doing anything to keep his mind fresh and go on learning from where and what he had learned at school.

The first thing to do is to buy him a diary and see that he writes it up every night, and if you have never kept one you will become enthusiastic about it and its records, and so will your son, and it will be an eye-opener as to how long it takes to do a certain paddock, how large it is, how it was worked, what wheat was sown, when stock were put in it, when moved out, the time the season broke, when dry spells occurred, the times of the mating of all farm animals, and in this way receiving gradually his education. Let him keep account of a certain paddock, cost of rent, taxes, and rates, feed consumed in fallowing, working, seeding, not forgetting his own wages, and both you and particularly the boy will know the wheat in the bag is not all profit as people are so often apt to pass judgment.

It may be said this is not necessary on a farm but it definitely is, for the city dweller is trained in all departments before he is started in his own business and, what is more, he has been getting all he earned, and the farmer of to-morrow will have to be treated the same if we are to hold him. If records such as mentioned were kept farmers would not suffer from land booms as in the past. Let the farmer of to-morrow take an interest in a few sidelines, and let him have pedigreed livestock and learn the art of judgment, selection, culling, feeding, and marketing, as well as cost and profit.

One only has to follow the work of the Home Project to see its value. We should have carried on from school keeping accounts and working out profit and loss until we could meet our city cousins on equal ground. Not one farmer's son in 10 can make out a balance-sheet, not because it is beyond their powers, but because they have not been taught or had the opportunity of learning.

[*Papers Read at Conferences.*]

The pioneers are often congratulated for what they have done, but what have many left to-day in their old age but poverty and worry? We want the settler of the right class and kind to go pioneering, and he will have to have conveniences and home comforts provided.

Circumstances have changed, and so will the application have to alter if the farmer of to-morrow is going to be competent and satisfied, for he must be trained in his business and be able to conduct that business, and in co-operation be able to maintain that freedom of action, spirit, and application so necessary to a contented and successful rural population.

The position is one-sided and is not going to last, for the farmer of to-morrow will be a slave and not a citizen of equal social standing as is his city cousin. And not until we see that our sons and brothers are better educated and equipped and catered for are we going to get the rights due to the farmers, their wives, and their children, nor will success be reached with land settlement. In working for this end, let it be taught that farming is a business or a life's work of development and industry, not a mine to be exploited, make a fortune, and then get rid of it. Instil into the mind of the farmer of to-morrow that he is engaged in an honourable business, and let him develop that feeling and pride that he must be educated and equipped to develop that farm more than ever, because it has been in the family name for so many generations.

AGRICULTURAL BUREAU CONFERENCE.

The Annual Conference of Branches of the Agricultural Bureau situated in non-irrigated fruit-growing districts was held at Balhannah on November 6th.

Mr. C. W. R. James presided and Mr. J. B. Murdoch (Advisory Board of Agriculture) delivered the opening address. There were also present Messrs. H. N. Wicks (Advisory Board of Agriculture), A. G. Strickland (Deputy Chief Horticultural Instructor), H. B. Barlow (Chief Dairy Instructor), R. Fowler, E. Leishman, H. H. Orchard, and J. B. Harris (District Horticultural Instructors), and H. C. Pritchard (General Secretary).

The following papers were read and discussed:—"Thrift," by Mr. W. G. Ahrens (Light's Pass); "Prevalence of Gummosis in the Barossa District," by Mr. Bert Boehm (Light's Pass); and "Some Points Worth Considering when planting an Apple Orchard," by Mr. C. G. Grasby (Balhannah).

Mr. Strickland replied to several questions dealing with the steps which are being taken to prevent the introduction of Oriental Peach Moth, methods of removing spray residues, the use of sulphur as a soil amendment or as a deterrent to insect or fungus pests, the cost of installing a central spraying outfit in a 50-acre orchard, and the control of pear bark canker.

The following resolutions were carried:—(1) "That it be a recommendation to all fruitgrowers to burn cuttings within one week after pruning"; (2) "that experiments be carried out on early and late ploughing for fruit trees"; (3) "that the next Conference be held at Lyndoch"; (4) "that the Government and all other landowners take all possible steps to eradicate cape tulip"; (5) "that the Postal Department be asked to relax the very rigid three-minute law in connection with trunk line telephone calls.""

In order to add to the educational value of the Conference and to illustrate the quality of produce of the district, the Balhannah Branch staged a most effective display of fresh fruit and many kinds of preserves. Trophies won by the Branch in various competitions were also on view, and a particularly attractive group of wood-turned articles, exhibiting skilled workmanship, engaged the special attention of delegates during the day.

DAIRY AND FARM PRODUCE MARKETS.

MESSRS. A. W. SANDFORD & Co. reported on November 1st, 1934:—

BUTTER.—Conditions in regard to dairying have very much improved during October as the general rains and absence of hot drying weather resulted in the feed growth being maintained, and, consequently, supplies of cream and butter kept up well. The season's production, however, in aggregate has been much less than last year, and the peak was reached last week. The London butter market has shown a little improvement owing to a better movement of trade in Germany and overseas prices advanced. This was reflected by a hardening in rates in the local markets, and, under the Equalization Plan better prices were paid for butterfat. Local print trade was well maintained throughout the month and also fairly regular supplies were sent to Broken Hill. Present prices in the Adelaide markets are:—Choicest creamery fresh butter in bulk, 1s. 2½d. per lb.; prints and delivery extra. (These prices are subject to Stabilization Levies.) Store and collectors' lots, 5d. to 5½d. per lb. according to quality.

CHEESE.—Considerable quantities were exported throughout October, and as production steadily increased, this lifting of surplus relieved market from week to week. Westralian buyers purchased regularly and local traders' requirements were met. The cheese manufacturers also have a plan operating for stabilising prices so that rates have continued steady at:—Large and medium, from 8d. per pound.; loaf, from 8½d. per pound at store door, delivery extra; semi-matured and matured, 8½d. to 9d. per pound.

BACON.—Turnover was well maintained and consumption was at a higher level than for October of last year. This was due to the fact that more bacon is consumed during the cool weather than during hot spells. Curers consigned ample supplies to the open markets, which were cleared from week to week. Increased interest was shown in hams both for current trade and for forward delivery and values for bacon and hams firmed during the month. Best quality sides, 9½d. to 9¾d. per pound; middles, 10¼d. to 10½d.; rolls, 8½d. to 9d.; hams, 1s. 1d. to 1s. 2d.; cooked, 1s. 3d. to 1s. 4d. per pound; lard prints, 5½d. per pound.

EGGS.—A strong demand continued throughout the month under review, and with exporters working at full pressure all that would pass the graders for quality were shipped abroad. Considerable quantities were manufactured into pulp and floors were kept nicely cleared from day to day. Production in eggs this season seems to be less than last season although a greater proportion has been exported. Values have fairly well maintained although there was an easing towards the end of the month. Present rates are:—Ordinary country eggs, fair average quality, 7d. per dozen net; long distance rail or shipping eggs, lower; Export quality, clean eggs, 1⅞ozs. and over, up to 9½d. per dozen net.

ALMONDS.—Moderate supplies were received from week to week, but good steady demand absorbed all that were offering, and values were steady at:—Softshells and Brandis, 9d. to 9½d. per pound; hardshells, 5½d. to 6d. per pound; kernels, 1s. 11½d. to 2s. 0½d. per pound.

HONEY.—Sales were disappointing, and considerable unsold stocks are held by merchants and also by apiarists. Rates are:—Prime quality clear extracted, 3d. to 3½d. per pound; lower grades, 2d. to 2½d. per pound.

BEESWAX.—Met with ready sale, although quantities offering were not very great. Values continue steady. 1s. 4d. to 1s. 4½d., according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Thursday, and Friday, and our sale rooms are the best equipped in the State. There is a specially strong demand at present for live poultry, and prices ruling are higher than for many months past. Supplies, at recent sales, have been short of requirements so that consignors are advised to forward any surplus straight away rather than delay until closer to Christmas. Crates loaned free on application. The following are rates realised:—Prime roosters, 4s. to 5s. 6d. ; nice-conditioned cockerels, 3s. 3d. to 3s. 10d.; fair-conditioned cockerels, 2s. 6d. to 3s. 2d.; chickens, lower; heavyweight hens, 3s. to 3s. 9d.; medium hens, 2s. 6d. to 3s.; light hens, 2s. 2d. to 2s. 5d.; couple of pens of weedy sorts, lower; prime young Muscovy drakes, 5s. to 6s. 6d.; young Muscovy ducks, 2s. 9d. to 3s. 9d.; ordinary ducks, 1s. 9d. to 2s. 9d.; ducklings, lower; geese, 3s. 6d. to 4s. 6d.; goslings, lower; turkeys, good to prime condition, 10d. to 1s. per pound live-weight; turkeys, fair condition, 7d. to 9d. per pound live-weight; turkeys, poor and crooked-breasted, lower; pigeons, 5d. to 7d. each.

POTATOES.—Good, old season's, 11s. per cwt.

ONIONS.—Good, old season's, 11s. per cwt.

RAINFALL TABLE.

The following figures, from data supplied by the Commonwealth Meteorological Department, show the rainfall at the subjoined stations for the month of October, 1934, also the average precipitation for October, and the average annual rainfall.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.

June 20th.—Attendance, 20.

FOX POISONING.—Paper read by Mr. R. Dinning:—"For best results in poisoning start before the lambing season commences or young rabbits are about for if left until then there are apparently some foxes that will only eat their own kill. For poisoning in summer or early autumn birds are a very satisfactory bait, especially parrots. For later poisoning nothing is equal to caul fat. A good trail is of special importance, for no matter how good the baits if foxes cannot find them your efforts are wasted. The full carcass of a sheep is good; a ram with horns is all the better. If a smaller trail has to be used drag something else as well to make a mark. A good trail is not necessarily a smelly one; a fresh carcass is far more effective. To prepare the baits I use strychnine crystals. It is quite simple to crush these in a bottle. Get a stick that will fit the mouth of the bottle, cut the end off level, and a few rubs will powder the lot. When using birds for baits cut open the breast and pace the poison inside. For caul fat I cut it into pieces that, when rolled up, make a bait about the size of a magpie's egg; just put the poison on one corner of the piece of fat, and then roll it up. If the fat has been kept in a bag so that it does not get cold it will make up readily, and will soon set once it is made into bait so that it can be thrown from a vehicle quite safely without opening up. Recently I put a number of butter baits on a ploughed field where it was easily seen that the foxes had followed the trail, but with no results. Two nights later I put caul fat baits on the same trail and got five the first night and others afterwards. In laying the baits drop them from the buggy, and if in a place where they have to be picked up I mark the spot with a hoe. About 100yds. apart is a fair distance between baits; if too close or if too much poison is used the foxes travel too far before dying, even if they do not recover. I use as much strychnine as will half cover a 3d. piece. I never use sticks for making the baits, but always the bare hands, and so far this year I know of 65 victims. Too much care cannot be taken with the dogs, and one must be out early in the morning, because crows are apt to pick up the baits and drop them anywhere."

Mr. H. Hinge read the following paper:—"Before commencing with the poisoning of foxes it is important for every landholder to start poisoning early in the season—say, about March and April. My experience shows that foxes may be on one property to-night and on someone else's the next night. Lambs can be saved by poisoning early. Last year we tailed 96 per cent. lambs, but this year I doubt if we will have any more than 60 or 70 per cent. I commenced poisoning last year in March, and found about 50 foxes; but this year I did not start until June. Perhaps this season was not so favourable for a good lambing, but I have found about 40 that the foxes have killed. Do not handle the baits by hand; and, secondly, use only fresh baits from a newly killed sheep. I have had my best luck in early poisoning by using kidney or caul fat. I take the fat while still warm, and cut into pieces about 1in. square; cut a slit, and insert the strychnine, about as much as will cover a 6d. piece. Crystal strychnine gives the best results, and is quite simple to make into a powder. It is a different matter to poison later in the season; the foxes are more cunning. During the last two years I have had excellent results by using young roosters for baits. This is not extravagant, but good value if you can get a 7s. 6d. fox skin for each one. To prepare them as baits, tap them on the head with a stick, being careful throughout not to touch them with the hands. While warm, put a small cut in the head, and also slit open the breast, and put in the poison, taking care to place it down on the liver, &c. Take them out in the paddock and place in thick patches of grass or any other cover that will hide them from the hawks. I put out two roosters, and after waiting over a week found a fox at each. It is important to poison early. If everyone did so the fox pest would soon be a very small one."

Discussion.—Mr. Hinge did not drag a trail when using roosters as baits. He walked and dragged the trail, and lightly covered the baits early in the year, but not later. Mr. Dinning had good results from parrots as baits, and had also found sparrows very satisfactory. Mr. Hinge related how he outwitted a wily old fox by deeply burying a steer and lightly burying some baits nearby. Both speakers agreed that the fresh material was best for the trail. Mr. Lucas asked if S.A.P. would poison foxes. Mr. Dinning said it would clean up crows, but was not suitable for foxes. For strychnine poisoning in dogs, Mr. Dinning used bluestone washed down by water, and Mr. Hinge used salt, followed by milk. Supper was provided by the Women's Branch. (Secretary, A. Ross.)

MIDDLE NORTH DISTRICT.

THE SUCCESSFUL TREATMENT AND PREVENTION OF MILK FEVER.

[*Paper read by Mr. E. W. Richards at the July Meeting of the Narridy Branch.*]

The condition known far and wide as milk fever is one that will always be of interest to the farmer who has good milkers, for it is a condition that seldom occurs among cows that give only a moderate amount of milk. While the condition has to do with milk, it has nothing to do with fever, for the cow that goes to the ground through this condition almost always has a subnormal temperature. The condition has probably existed in past ages, but it has undoubtedly become much more common during the last 50 years, since breeding and selection and feeding have aided the evolution of these new breeds in which the cows give gallons where formally they gave only pints. This increase in the quantity of milk is the keynote which explains the increase in frequency of this condition.

HISTORICAL.

In 1897 there lived in Kolding, Denmark, a veterinary practitioner named J. J. Smidt. At this period bacteria had become fashionable, for the great Lister had introduced his antiseptic practice, and no disease was considered complete unless it had a germ of its own for its causation. Lister's (1827-1912) discovery was that in his day a serious operation meant almost certain death, because almost invariably putrefaction and blood poisoning occurred in the wound made by the surgeon's knife. Lister made the epoch-making discovery that these evils were the result of germs, and that by the use of carbolic acid the wound could be kept antiseptic and proof against action of germs. But for the general use of antiseptics in surgery, which followed Lister's discovery, most of the operations which are now common practice in hospitals could not be attempted at all.

Smidt accordingly reasoned that as milk fever appeared soon after the calf was born, during the days in which the first milk was drawn from the udder, therefore milk fever must be closely related to milk secretion, and the cow's udder must be the seat of germ invasion. By examining the milk of the affected cows with the microscope and finding some large cells in the milk in addition to the usual small ones, he came to the conclusion that the germs infested the udder and caused the cells which secrete the milk to be affected. Had Smidt known more he would have realised that the large cells which he saw floating about in the milk when he examined it by the microscope were the usual cells found in the first milk secreted—colostrum. But it was lucky that he did not know too much, because he at once essayed to kill imaginary germs in the cow's udder by injecting into the udder a solution of iodine of potassium, which he thought would prove a germ killer. To the great joy of Smidt, he immediately obtained splendid results, for all the injected cows recovered, and the good news soon spread far and wide, and many cows' udders were injected. The triumph of his theory was not long lived, for Anderson, of Skanderborg (Denmark) found that it was unnecessary to use the potassium iodide solution, because air pumped into the udder by way of the teats was just as effective; in fact, it had an advantage because the mammary glands (udder) did not suffer so often from mammitis, after air injections. Thus was introduced one of the most remarkable methods of treatment to be found in the whole of veterinary medicine, and this inflation of the udder is the treatment almost universally used by the farmers.

SYMPTOMS, AND TREATMENT BY AIR.

Milk fever is a very common and until recently frequently fatal disease affecting cows, while cases have been known in goats and pigs. As it attacks only the best milkers it causes a severe loss to our dairying industry. It is therefore of great economic importance that dairymen should acquaint themselves with its successful treatment and better still, prevention. It is the disease of heavy milking, well fed cows, and generally occurs between the third to seventh calf, the most active period of the cow. It is confined to heavy milkers.

The earlier symptoms are very often not recognised by the dairyman. At the commencement the animal becomes excited and restless, treads with the hind feet, switches her tail and stares around. She may bellow occasionally and show slight colicky pains. These are followed by weakness at the joints and finally paralysis.

The symptom that is the greatest aid in the diagnosis of the cow is the characteristic position assumed. The head is turned around to the side (usually the left) and rests on the chest causing a peculiar arching of the neck. The body rests slightly on one side, with the hind legs extended forward and outward, and the front legs in

their normal position. The eye is very dull and staring. A drench of 1 cup of coffee boiled in 1 pint of water for 15 minutes and given carefully is a great stimulant to the beast. Milk fever usually occurs within two or three days of calving.

The very successful treatment used by us at present is, when a cow is found down, to disinfect the udder and hands, then inflate the udder with sterilised air by using a milk fever outfit consisting of a needle, air steriliser filled with cotton wool dipped in disinfectant, and a pump. In the absence of the outfit, a bicycle pump and valve may be used, but there is more danger from infections such as mammitis. The udder should be kept inflated until the cow rises, which is usually as long after treatment as she was down before. Strong coffee may be given as a stimulant if the cow appears to be sinking. The beast may die after being down from 18 to 20 hours. This is a successful treatment, but tests show it may impair the milk supply.

THE BIOCHEMISTRY OF MILK.

Milk is a fluid secreted by the mammary glands, but it is not merely filtered fluid from the blood plasma (fluid of blood); the water in blood supplies its bulk, which constitutes 87 per cent. of the milk of the cow. I desire to concentrate attention on its mineral constituents, more especially calcium and in a lesser degree phosphorus, which usually work together.

Calcium exists in the fluid part of the blood in organic combination with the phosphates. It is obvious that the cow when carrying her calf must have a good amount of calcium in her blood so as to supply her calf with calcium, which must be deposited in its bones, especially during the later months of the gestation period.

When fodder is plentiful and the cow is well fed, she takes in more calcium than is required for her daily needs and by the action of vitamin D the calcium is deposited in the long bones of the cow and in other places that act as storehouses for it. By this arrangement the cow can supply the calf, while still unborn, with all the lime that its bones require, and there is still a supply for the milk when it starts to flow after the calf is born.

When, however, the feed is poor and the cow is compelled to live on any grass available she may not receive sufficient lime for her wants, and while still carrying her calf she will be called upon to yield up some of the lime from her own bones, probably leading to that deficiency disease, osteomalacia, and when the calf is born it will have rickets.

It is well known that cows that have been ill-fed and which give only a fair quantity of milk are not troubled with milk fever, but the well-fed cow that gives large quantities of milk is the one that falls victim to this complaint.

She may have been given plenty of calcium in her food and yet within 20 to 40 hours after the calf is born she is found on the ground and unable to rise.

This condition has long been a puzzle, and it is only during the last few years that the cause of the trouble has been worked out, chiefly by Professor Greig of Edinburgh. There have been at least 20 theories to account for it, but the real one explains why milk fever is no fever, but a deficiency disease, due to lack of calcium in the blood.

Observations by biochemists have shown that, when a cow is in good health, if her blood be analysed, it will contain 10 millegrams of calcium per 100 cubic centimetres of blood plasma. If, however, it comes about that the calcium is reduced to 5 millegrams, the cow exhibits the symptoms of milk fever.

Anderson found that, when he emptied the udder of its milk, and then pumped up each teat with air, the cows recovered, but it was not until recently the explanation of this cure has been put forward. It is known that if a cow has a large quantity of milk in her udder soon after the calf is born and this is withdrawn at one milking, the cow often develops milk fever. If, on the other hand, only a small quantity of milk is drawn off and this repeated every 4 hours for a couple of days the cow does not develop milk fever symptoms so frequently.

The explanation of the effect of inflating the udder is quite clear. The air injected into the udder causes pressure on the blood vessels and thereby the quantity of milk secreted is much reduced, As the milk secreted is less, the quantity of calcium withdrawn from the blood is less, and this gives the endocrine glands that preside over the secretion of milk and over the mobilisation of calcium from the bones, time to restore the calcium to its proper percentage in the blood. With this restoration, the symptoms disappear. When a cow goes down with milk fever, it is now not necessary to use the pump to inflate her udder, all that is needed is to inject 300 grains of calcium gluconate dissolved in 12ozs. of distilled or boiled water, under the skin of the cow just in front of her shoulder blade, and when this has been absorbed into the blood, the cow will

throw off all the symptoms of milk fever and get up quite well. The reason is obvious. The calcium has been absorbed in the blood, and the percentage of calcium in the blood restored and all is well. There is no theory about this, it is proof for Professor Greig's experiments show that it is a treatment that is almost invariably successful.

Recently, in Lismore, New South Wales, Mr. Stewart McKay has been writing a series of papers endeavouring to persuade dairy farmers, who have valuable cows, to inject them 12 hours after calving to try and prevent the symptoms of milk fever appearing. The treatment is quite logical. Milk fever is due to the sudden call on the calcium of the blood by the milk secreted during the first days, and this call is so insistent that the calcium stored in the bones of the cow's limbs is not able to be mobilised quickly enough to supply the blood with enough calcium to keep the percentage up above 5 or 6 millegrams per 100 cubic centimetres, and so the cow gradually goes to the ground. If, while the calcium is being withdrawn from the blood, we inject calcium in a form that readily absorbs into the blood, we counteract the bad effects of the withdrawal by restoring the percentage in the blood.

The injection is easily made. It can be made into a vein if a veterinary surgeon does it, but farmers will find the following plan very easy. All that is needed is the apparatus and 300 grains of calcium gluconate dissolved in 12ozs. of distilled water or boiled water. Shave a square inch of the cow's hide in front of the shoulder blade or anywhere else it is found that the hide can be easily pulled up. Thoroughly cleanse the bare spot by washing it with hot water and soft soap, and then disinfect it with tincture of iodine. In the meantime the apparatus is prepared. It consists of a glass reservoir holding 12ozs.; to the bottom of this is attached a rubber tube and to the lower end of the tube is affixed a hollow needle some 3in. long. The whole equipment must be boiled. The fluid is poured into the reservoir and the rubber tube pinched near the needle to prevent the fluid escaping. Then plunge the needle into the hide in a slanting direction so that an inch or more of it will lie immediately under the skin. The solution is allowed to run into the loose cellular tissue which lies between the hide and the muscles. Care should be exercised not to push the needle into the muscle because the fluid will not run into the muscle as easily as it does just under the skin.

Colt Breaking.—The following paper was read by Mr. N. Stewart:—"When the majority of primary producers have to look to horse power for strength for the working of the land, colt breaking and handling does not receive proper attention. In many cases the colt is left to run in the paddock until the autumn rains fall, and then is often put straight to team work to do the work of a tried worker. The colt should not be handled more than necessary before it is to be prepared for work, and if at all possible not be allowed in the stable while sucking the mare. Hand feed by all means, but have other places than in a stable with the working horses to do it. The best age for preparing the colt is rising 3-year old. During spring the colt should be driven into a stall where it can be easily caught. A strong rope is essential, and I favour a pair of winkers instead of an open head stall. Tie the colt firmly to a good post in the stall and do not free it until it understands that the rope is there for a purpose. The tail can be drawn, brushed, and combed. This will give the animal confidence and its fear will soon depart. I do not favour mouthing a colt; it is a cruel way of mastering the animal. After leaving the stall, the colt should be first taught to lead. Not much patience is required before it can be led to water. It should then be harnessed and allowed to roam around the yard with a long chain on each side of it to which it will soon become accustomed, and in most cases will not kick at a chain afterwards. I favour putting the colt in the shafts of the wagon for a short period each day; there it can learn what stop and start means and to back. In most cases it will pull on its own account; it should then be ready to take short yoke in the back of a tandem team on the cultivator. A tandem team relieves all the strain of the bit and will do much towards avoiding a sore mouth. The near side in the back is the proper position until it understands what is expected of it. It should only be worked short yokes and not every day for a start. It should be given its freedom through the summer and with handfeeding prior to the commencement of work the following autumn should be easily caught and harnessed and be ready to

take its place in the team. If these suggestions are followed the colt will return good work to the driver as a faithful servant to whom a little consideration and patience have been shown in the time it did not understand what was expected of it.'' (Secretary, C. Jericho.)

TAPLAN.

July 11th.—Attendance, 15.

EFFICIENCY AND THE PLIGHT OF THE FARMER.—Paper read by Mr. P. R. Hodge (Hon. Secretary):—''The present sorry plight in which the farmer finds himself to-day is due to many causes, as stressed time and again by the various witnesses before the recent Royal Commission on the Wheat Industry. We all know by reading the daily papers, what most of these items are, but few of us are willing to admit to another cause which, to my mind, is one of the main ones, and that is inefficiency. Through various causes and disabilities he finds that it is impossible to do the job as he would like to and knows he should do. Through lack of finance he cannot buy the most suitable implement for the job and has to carry on with an out of date or obsolete machine, when a more modern one would do the job more efficiently, and more economically. The majority of teams in our district are much below strength, through losses, and the remaining horses are in many cases much older than they should be to do the job required of them. Most farmers, too, are unable at present to fence their blocks for the keeping of sheep, or else cannot get the necessary finance for the purchase of them. This means not only a distinct loss of revenue to the farmer, but also prevents him from working his place to the greatest and most profitable advantage, for sheep undoubtedly are one of the main assets of the farmer under present conditions. They not only provide finance when most needed besides meat for the household, but also do valuable work on the fallow, which would otherwise often necessitate the dragging over of a big team and implements. The job is also being done at the right time, as it quite often happens that rain falls when it is not possible to work the fallow, and the sheep have to take the place of the working which may be necessary. Farm buildings probably are not nearly so convenient as may be desired or as they would be had the owner the finance to make them so. We find on moving round the district that buildings in many cases have ceased to carry out the job for which they were built, and the farmer is at a loss to know how he is to renew them. The fact that he is unable at present to do so very often causes serious inconvenience and considerably more work than should be necessary. The same applies to harness and other equipment for the farm, much of which is getting beyond repair. One could go on enumerating these disabilities under which we are all more or less working, and they all lead to inefficiency. How then can we hope to make a success of farming under these conditions? It is an impossibility, but it is possible that in many cases our actual farming methods can be improved on, and in other cases where lack of finance forbids it we can at least aim at better methods. In this regard we must admit that too much unfallowed land is cropped in our district, and it does not need any long itemising of tests and trials to prove this. It has been proved time and again that fallow land produces crops, and often good crops, while stubble and grass land fail. Some of us may not be able through any of the disabilities mentioned earlier, to fallow as much as our neighbour, but we can at least do what we are able to do, thoroughly. The fallowing of more land may necessarily reduce the acreage available for cropping, and this would be in the best interests of the industry and all concerned, for the cropping and handling of the crop, could be done much more economically than the bigger area of stubble and fallow, for probably the same return. The smaller cropping area would in turn allow more time for the proper working of the fallow. In our effort to get as much fallow as possible, however, we must not overlook the matter of how much we can reasonably make a good job of, and keep in good condition, with the plant at our disposal. This is where many of us fail, just as badly as by trying to crop more than we reasonably can, and as a consequence much fallow is cropped which is an insult to the name. Nothing is more pleasing to the eye than a paddock of good clean fallow, and nothing more distasteful than one of unattended fallow. It is unfortunately a fact that some farmers with their present methods could not make a success of it, even under normal conditions, let alone present ones, but if good farming methods are adopted it will probably be possible to hold on through the bad period until conditions improve. In this respect I cite neither my own nor any one else's cases, but I feel certain that no matter what our present or ultimate

position may be, if we aim at the best methods we must sooner or later reap our reward, for method leads to efficiency, and efficiency to success. If it is only in one of the many items connected with our means of livelihood that we can improve, we will get much satisfaction from the fact that it will lead us on to more improvement ventures and ultimate success.''

Di-Calcic Phosphate—A Lick for Stock.—Paper read by Mr. V. Tapscott:—''For many years I have been trying to find something that would prevent cattle from chewing bones, sticks and stones. I tried salt, bone meal and licks without success. The bone meal and licks are rather expensive and some cows will not touch bone meal, nor will horses or sheep. Last year I gave the milking cows a little phosphate in their feed every night and it seemed to work very well, but it contained too much sand. The following is a recommendation of the West Australian Department of Agriculture. Where used as a composite lick made up of 40 parts di-calcic phosphate, 60 parts salt, the following directions are recommended. A few pounds of Epsom salts mixed with the above is an improvement. Milking cows, 4ozs. per cow per day—mixed with food; dry cattle, 4ozs. per cow per day during dry season. Sheep, ½oz. per sheep per day. When there is plenty of green feed it is not necessary or wise to give the lick. I have used this lick with excellent results. The cows are in better form and never seem to be looking for anything to chew. Sheep and horses take readily to it; my horses are in better condition this season than they have been for some time. For sheep, horses, and dry cattle, I put the lick in boxes out in the paddock, the rain does not wash it away but sets it into a hard cake which forms a lick. I have been using it now for about 4 months, and if stock owners were to give it a trial during summer they would be more than pleased with the results. I have fed my cows with loose hay and sprinkled the mixture on the hay, damping it down with water, then the di-calcic and salt clings to the hay. A small tin that will just hold 4ozs. can be used for measuring the mixture for each cow. The price of di-calcic is about 16s. 6d., salt 5s. per bag.'' (Secretary, T. A. Philps.)

SCOTT'S BOTTOM.

Mendelism.—Mr. Blakeley read the following paper:—''That children resemble their parents in some degree is a well-known fact. The physical and mental characteristics of some children are similar to those of their grand-parents and even great-grand-parents. The same may be said of animals and plants. Mendelism is the name given to the science of hereditary factors in plants; named after Gregor Mendel, Austrian abbot, and naturalist. From the time of Aristotle, the Greek Philosopher, who, three centuries before Christ, made a rough classification of animals and plants, to the 17th century when John Ray, an Englishman, made a beginning; very little was discovered in the science of natural history. In the 18th century, botany as an exact science began. Carol Von Linne, better known as Linnaeus, was the first great botanist who classified plants. He grouped the plants in different orders according to their sex organs, but hinted that his grouping was only provisional and elementary. When he died in 1778, England purchased his works which included 2,000 books, 14,000 plants and 7,000 specimens of shells, animals and insects. The Linnean Society was founded and named in honour of this great Swedish naturalist. The work that Linnaeus had started of bringing order out of confusion, and comparing species with species from all parts of the world, inspired the work of Charles Darwin who in 1895 submitted a paper to the Linnean Society, which caused a great controversy in the realms of natural science. Linnaeus, Sir Robert Owen, and other naturalists of the day believed that species never changed. Darwin, after years of study and collecting, showed that plants and animals respond to their environment. Gradually plants would change and the accumulation of differences would produce a new species. During this controversy Gregor Mendel was studying plants in his monastery garden at Brunn. In the world of science he was almost unknown. He observed the way in which plants handed on their qualities to their descendants. In 1869 he published his work and sent copies of it to the various learned societies in Europe. His work failed to win recognition, and Mendel became very bitter. He died in 1884 knowing that his work would open up a new field in science. Unfortunately Darwin never saw Mendel's work. Had these two great men met, each would have found the final solution of their life's study. In 1900 Mendel's

work was revived and his name given to the laws which he first discovered. His teachings are now accepted by men of science, and have been the means of producing new varieties of plants and fruit to enrich the staple food of mankind. Some of the experiments performed by Mendel were with sweet peas. He crossed a pure-bred tall sweet-pea with a dwarf sweet-pea. The offsprings were tall. He called this quality of the first generation dominant, and the quality of the parent, that is dwarfness, that it did not exhibit, recessive. When seeds of the first generation were planted they produce a certain number of dwarf plants, in the ratio of one quarter tall dominant and one quarter dwarf dominant. The other two quarters when planted reproduced both dwarf and tall. These experiments and laws were taken as a basis for improving plants. Mendel also proved that plants could reproduce from generation to generation without change. Thus the tendency to dwarfness or tall growing have their origin in the germ cells. He also discovered in the case of sweet peas and beans that the dwarf or tall tendency could be carried in the male element or female element of the plants, and it did not matter whether the pollen was transferred to the ovule or *vice versa*. The study of Mendelism has had far reaching results. The various wheats, roses and fruits that have been improved are too numerous to mention. Luther Burbank, the great American botanist, is perhaps the greatest of plant breeders. He improved wheat, walnuts, roses and plums. The patience and industry of the men of science working to benefit the man on the land and mankind in general is worthy of high comment. Without research, the man on the land would not advance far. Agricultural institutions where this is done often come in for adverse criticism, but it is a note-worthy fact that of all the new varieties of wheat produced in South Australia the majority and most successful have been Roseworthy bred.''

On May 26th, Mr. H. H. Orchard (District Instructor) delivered an address ''Potato Cultivation.''

Eight members attended the meeting held on June 23rd when a paper ''Ailments of Stock'' was read by Mr. Mitchell. (Secretary, E. Atkinson.)

TUESDAY, OCTOBER 9th.

MORNING SESSION.

Delegates attended the Way Hall, and listened to an address, "Generalities Concerning Farm Poultry," by Mr. C. F. Anderson (Government Poultry Expert), after which they visited Mr. V. Gameau's poultry farm at Woodville.

AFTERNOON SESSION.

The Tuesday afternoon and following sessions were held in the A.N.A. Hall, Flinders Street, Adelaide,

Mrs. J. S. Hammatt, of the Williamstown Branch, was elected President, and Miss E. Lenihan, of the Department of Agriculture, acted as Secretary.

Mr. S. T. Gooden, Manager of the Wallpaper Department of Messrs. A. E. Clarkson Ltd., gave a talk, "Decorations for the Country Home."

LITERATURE IN THE HOME.

[MRS. N. M. KEYNES, Wirrabara.]

What pictures the words call up! One woman will look back on a time when books were brought from the school library and were began before her reluctant feet took her home, where the evening chores awaited the schoolgirl. Maybe another page or two could be snatched while the elders conversed after the evening meal, and if one was lucky a chapter or two before bedtime. Failing a library book, there were the books on the shelves read over and over again.

Another woman remembers a father who liked a thriller or a mother who loved romance. Then books came from the nearest circulating library, or they came from somewhere, for such people cannot live without books. The schoolgirl was not supposed to read these but, being the true daughter of these romantics, managed to get more than an inkling of their contents.

Perhaps the weekly paper was the only reading in which the family indulged. How it was conned from cover to cover! Another will not be able to remember a time when the little family did not group itself around an elder's knee, and their young minds drink in tales of enchantment.

Of all the privileges we enjoy there is none perhaps for which we ought to be more thankful than for books; to the real lover of them they are friends. In the narrow circle of our lives we cannot but seldom know the people we would—those inspiring people with whom we are at our best—but on the shelves the great minds wait patiently to give their treasures to whoever seeks them. Yet one sadly thinks how few people there are but who would think twice of spending the price of a joint of meat, or of an article of dress, fancied perhaps but not needed, or the price of an evening's entertainment, on a good book. Yet the book is a possession for life.

"But we must have food," we say, and "We must dress as other people dress." Yes, we must have food, and a great writer has said that "the sense of being well dressed gives a woman a feeling of tranquility which religion is powerless to bestow." I fear me that the man read us aright! Do let us reflect now and then that our minds are our real selves; do not let us starve these real selves, and lavish more than enough of food and clothes on the envelopes—our bodies.

The Home Library.

In building up a little home library, though tastes differ, what every household needs are reference books:—A dictionary to commence with, an encyclopaedia, a map or good atlas.

It is surprising how often even well-educated people misspell, and there can be nobody who does not need to look up a word now and then. But let us do more than that—a dictionary is the most interesting book. Let us study it now and then. Look for the meaning of words we are not familiar with; adventure with new ones; introduce them into our conversation.

There is a wealth of words to express every shade of meaning, yet how limited is our vocabulary! How we overwork a few adjectives; "nice," for instance; a nice woman, a nice cake, a nice dress, nice butter—all within five minutes!

Years ago a university student described everything that did not suit her as "rotten." Other words have come and gone since then; "putrid" and "poisonous" amonst them.

A cultured Indian whose English was a joy to hear was preparing for Oxford some Indian boys. He warned them of the ugliness of English speech, instancing the words "beast" and "beastly" as being common expressions. He told them they must set an example of purity in the English language when in England. These are among the people we give our pennies to help convert!

The Encyclopaedia.

An encyclopaedia on our shelves and a map on our walls, if in constant use, is a liberal education to a household, and even the boy whose interests seem centred in the doings of the cricket and football teams will follow on the map the flight of the aviator, the track of a ship, or maybe in response to father's request will finger his way to the site of the latest volcanic or political upheaval. Personally, if it were the only book or books that could be bought, I should buy an encyclopaedia, and depend on the circulating library for a time for other books.

Think of the satisfaction of being able to find an answer to most of the questions that crop up! Where does this or that come from; from what country and which part? Where is such a city or river? When and where did that man live, and what did he do to justify fame? If there is a student in the home an encyclopaedia is indispensable.

The following is a list of some of these books:—"Collins's New University Encyclopaedia with World Atlas," 1,376 pages in one volume, 9s. 6d.; "Routledge's Universal Encyclopaedia," 1,184 pages, 16 coloured maps, 3,110 illustrations, 11s. 3d.; "The Everyman's Encyclopaedia," strongly bound, printed on good paper, 12 volumes, £4 19s. 6d.; 1 folding map, 2s. 9d.; "Philip's League of Nations Handmap of the World," price 6d.; on rollers, small schoolroom map, 13s. 6d.; larger, 42in. x 52in., 24s.

There are other household reference books. If one is not satisfied with the gardening notes in the daily or weekly papers—which can be cut out and pasted in a blank book—no better book can be bought than Brunning's "Australian Gardener" at 7s. 6d. Cookery books almost every woman possesses. The cookery and domestic articles in the papers are so excellent that one cannot do better than preserve them. Never have we been so well served in this way.

If a member of the household is interested in any subject, be it bees or birds, flowers or trees, rocks or minerals, photography, machinery, drawing, or painting, let us not be satisfied until the book to help along the interest has been obtained. "Leach's Bird Book," for instance, costs but a few shillings. I have known someone who did not know more than one or two, and after a few years' observations and with the help of the book became familiar with the names and the habits of every bird seen in the district.

Some may like to refer to a book of etiquette, and being able to do so may save us mental anguish in unfamiliar situations, and it is reassuring to know how to begin and end some special letter.

A medical book should find a place on the shelves, not to rely on it as a substitute for a doctor when he is required, but often his services may be unnecessary, and on the other hand unsuspected dangers may be exposed. There are several good medical books, especially about babies—Truby King's being unsurpassed. The New Zealand women gave a beautifully bound copy to the Duchess of York when she visited that country.

People who have the care of animals should always have the best veterinary guides, especially where advice cannot be easily obtained.

Before dealing with general reading let me refer to those books written for children who are beginning to inquire from whence they have come It is a natural question from the child of four or five onwards, and if the parent evades the question, or tells the child lies, and later the child ceases to question we can be pretty sure someone else has answered it, and the child thinks there is something disgraceful about the business of coming into the world.

If the parent has difficulty in answering in a perfectly matter of fact way buy "The Cradle Ship," by Edith Howes, and read it, or if the child is able to read allow it to read the book, which has been strongly recommended. I have read it to young children in my case, and they absorb the knowledge as naturally as any other knowledge, and have not dwelt on the subject.

This course is the chief safeguard against the whispered, unpleasant story of some less fortunate child, who has not been told the truth. Edith Howes has also written some useful books for boys entering in their teens.

While on this subject it would be well to remember that there are papers which should never be taken into a home, especially where there are children—papers which depend for their circulation on the quantity of gutter news they print. Would we keep the garbage tin in the house? It would perhaps do less harm than some of the books and papers which find their way there.

Books for Girls.

Then, too, we must not let our girls be rushed into womanhood by reading trashy, sentimental novels. Few realise that such reading and the watching of prolonged love making on the screen is likely to hasten the young girl over the border which separates childhood and womanhood.

Psychologists say it is better to keep them children as long as is natural, and not let them be rushed into feelings they have not the wisdom or balance to control.

It is a particularly wholesome sign in a girl when she enjoys boy's books, and here, in passing, let us note that the average boy despises girls' books, and when he does read one it is usually accompanied by contemptuous snorts.

Some of you may have had the pleasure lately of listening in to a broadcast talk by the Director of Education. I saw the report in the "Advertiser." Mr. Adey said: "Every boy and girl should be encouraged to read real tales of adventure so long as these stories enshrined worthy ideals of conduct. There is still much to conquer in Australia, and the bold spirit of adventure is needed in every phase of national life. There is need for a literature that will fire the

youthful mind to leave the enervating city life and face dangers, and if it is to be produced the young people of to-day must master the secrets of great writers and in turn yield like treasures from their own minds." So it is for us to see that in these impressionable years that the right books to help our young people should be put in their way.

It is a significant fact that until the end of the 18th century, children were scarcely heard of in literature, and let us also remember that half of the children born died in infancy.

It would almost seem that Wordsworth was the Pied Piper who led the children into their kingdom:—

"Trailing clouds of glory do we come
From God, Who is our home;
Heaven lies about us in our infancy."

Then how quickly the English language was enriched! In many of the greatest books children were the leading characters. Dickens has a host of them:—Little Nell, Paul Dombey, David Copperfield, the fat boy, and many another; children who with George Elliot's Maggie and Tom Tullever and Bronte's Jane Eyre might almost be called the nation's children.

Do not let the children be shut out from this magic world until they can read for themselves. Let us remember the first seven years are the most important ones. Let simple Bible stories be a foundation, and here may be mentioned that Arthur Mee's "Bible for Children" is a precious possession for adults as well.

Such books as Kipling's "Just-so Stories," "The Wind in the Willows," "Alice in Wonderland," and that most beautiful of all children's books, "Hans Andersen's Stories"—Queen Alexandra's favourite book—can be enjoyed at five or at 50. Surely every girl would love "Little Women" and "Good Wives" and "What Katy Did"—books which have delighted four generations. There are Ethel Turner's earlier books, and Emily Montgomery, and a long list of school stories.

Books for Boys.

For the boy reaching out into life there is wealth indeed! "Robinson Crusoe," written 200 years ago, has delighted generation after generation. "Lorna Doone" they must not miss. "The Arabian Nights," Sir Walter Scott's books, Ballantine, Stevenson, Herbert Strang, Mark Twain. I can name but a few. All have written what is worth buying.

There is a delightful and instructive newspaper published by Arthur Mee. It is 17s. 6d per year, and an easier, more interesting way of putting the world's doings before these citizens-to-be cannot be found. Nearly every book mentioned can be bought well bound and typed in the "Collins Classics," at 2s. 6d.; "The World's Classics," at 3s.; "Everyman's Library," 3s.; "Nelson's Library," 2s. 3d.; "People's Library," 3s. Kipling's books are not in the cheaper editions.

To the young people in the upper classes of the Primary School with High School looming ahead, "Cassell's Book of Knowledge" is a gold mine, and will help them over many a hard place, as well as fill many an hour instructively. It is expensive bought new—about £8 for the eight large volumes. I know of one parent who put a 1s. advertisement in the "Wanted to Buy" column, and through it purchased an unused set for £3 10s.

Boys and girls, and the grown-ups as well, should read animal stories. Anyone who has read that beautiful book "Black Beauty" would not thoughtlessly turn out an old horse to die uncared for. "Owd Bob" is a powerful story of dogs and their shepherd masters, and the great love between them. "The Call of the Wild" and "White Fang," Jack London's earlier books; "Bambi," a story of deer and their terror of man, are some of the books that will help to remind us that here are God's creatures as well as ourselves—"little

brothers," the gentle St. Francis calls them. How important that children should be taught to be gentle, loving, and humane, and there is not a better way of doing this than by teaching them kindness to animals!

All the books, except one or two, are published in the cheaper editions, and when on a visit to town it is a good plan to inspect them and buy some. Depend on the circulating library if you like for the books of the hour which are the peculiar possession of the age, and for which we should be thankful, but if you are a reader buy the standard books. They are books with a soul—books that inspire, entertain, and satisfy. If they are to our hand we are more likely to read and re-read.

The worth-while books make us broader in our outlook, widen our sympathies, deepen our penetration, increase our reverence, and after years of this we find we are thinking for ourselves; that we have grown up; that our minds are no longer merely a cold storage plant for the thoughts of others, but a powerhouse for our own.

MORNING SESSION.

WEDNESDAY, OCTOBER 10th.

THE PLANNING OF A HOME.

An Address Delivered by Mr. Norman C. Fisher, A.R.I.B.A., A.R.A.I.A.,

In dealing with this subject, I readily appreciate the fact that my audience is drawn from the far corners of South Australia, and that the conditions under which many of you work and live probably vary considerably.

Time will not permit me to deal exhaustively with the subject, so that I ask that my remarks be regarded as a general outline only. Some of them may not apply to your own particular circumstances, others you may regard as being the obvious; but, nevertheless I trust that at least a little of what I say may be helpful to all of you.

The provision of shelter for man and his family is a problem which has confronted us since our ancestors swung themselves by their tails from tree to tree. Throughout the ages, however, the desire to improve one's conditions of living has exerted itself, until to-day the *planning, equipment and furnishing* of a home, whether it be small or large, country or suburban, is a subject which is very dear to the heart of the average woman.

In dealing with the question of home planning, let me make it quite clear at the outset that there are no golden rules, firm and immovable, that can and must be followed; rather we must regard each problem separately and on its own particular merits, with certain broad principles only, to aid us in our decisions.

The question of *site* is the first factor of major importance. You will readily appreciate that in the selection of a building site the owner is embarking on a project of no mean magnitude, and that it requires the very closest investigation into numbers of factors that will at some time or other affect the comfort of the occupants.

The suburban owner is faced with the possible development or otherwise of the district, for on that will depend the value of his investment. Women sometimes inquire into the social possibilities. Rates and taxes must be assessed, and travelling time and costs to and from business must be considered. Frequently these points are neglected, or else the attraction of the apparently cheap block proves to be too much for the prospective home builder, and he succumbs. Some of these factors fortunately do not bother you, but the fact remains that too many people conceive the plan of their home without any regard whatsoever to site or position.

No home should be planned until the position of the site and its relation to the points of the compass is determined, whether in the proverbial "40-acre paddock" or on a small allotment.

A flat site or one on a hillside present entirely different problems, the regular shaped site and the irregular still further problems, and then local conditions, such as winds, natural shade, protection by trees and hillsides, and the general configuration of the locality are all serious factors in the early deliberation on this subject.

The Aspect of a Home Should Determine the Disposition of the Various Departments.

Just as a modern factory is planned in relation to transport facilities, and the progressive processes of manufacture and distribution, so can the departments of a home be allocated in a similar manner.

The average home consists of living, sleeping and working quarters. Their nature and position should be determined by the personal likes and dislikes of the owner, by the particular habits of the home, and by the degree of assistance rendered by servants, whether manual or mechanical.

Let us then consider the functions of the various dispositions of our plan:—

The housewife probably regards the commissariat department as the most important of the house. Under this heading we include food reception, storage, preparation and service.

In South Australia the usual custom is to serve a hot dinner in the evening. This means that the greater portion of the preparation of this meal is done in the afternoon. As the kitchen is at the best of times the warmest room in the house, it reasonably follows that every provision should be made for keeping it naturally cool at that period when it is most continuously used. Generally speaking, the summer planning of this room should receive primary consideration.

The usual summer afternoon breezes are easterly; therefore, if possible, the kitchen should be in such a position on the southerly or cool side of the house, to take advantage of cooling breezes during the hot period.

Bedrooms should not, in my opinion, be placed on the southerly side. For the greater portion of the year it is impossible for the sun to enter these rooms, and if they are utilised as sleeping rooms, and not merely dressing rooms, this is a distinct disadvantage.

An easterly aspect for bedrooms is good. The early morning sun can at least enter the room and lend a genial air sufficient to enable early risers to do so with some degree of willingness, and are sufficiently protected from the general heat of the day to render them comfortably cool enough when it is time to retire.

The position of a sleep-out, however, provides a good deal of discussion and differences of opinion. Used chiefly as summer sleeping quarters, consideration is due to obtaining the maximum benefit from whatever cooling breezes there may be. In the eastern suburbs of Adelaide the much-abused gully winds have certain virtues, in so far that they do provide quick cooling, whilst at the seaside and other situations the prevailing evening breezes are frequently south-westerly. Generally speaking, the south-westerly situation is one which affords the most general satisfaction in the use of a sleep-out.

The Functions of Rooms.

The preference of people to regard the dining room solely as a mealing room renders the need for this to be planned as a large room quite unnecessary.

The living room has become a common feature of the average home, and if the purse be sufficiently deep, used in conjunction with a smaller and cosy den, or smoke-room. The formal drawing room is an additional luxury if it can be afforded.

Working quarters, consisting of kitchen, pantry or store, perhaps a cellar or cool room, scullery, and servery should receive very careful consideration.

With sufficient thought in respect to the proper size and disposition of the most used sections of this department, the energy of those responsible for its proper working can be very considerably conserved. I am a firm believer in the long narrow-shaped kitchen, in which the progressive processes of food preparation, cooking and service to the mealing room can be carried out with a minimum of tramping across a wide room.

Great credit must be given to the Americans for their endeavours to bring the kitchen to a very high state of efficient planning and operation.

We, as good Australians, sometimes unduly flatter ourselves as to the general excellence of the climate that we enjoy. Undoubtedly we have one of the most temperate climates in the world; but are we not unwise, unless we plan to intelligently provide against the excesses of heat and cold which are sometimes inflicted on us? To disregard these two factors is to submit to extremely uncomfortable and unnecessary conditions. In regard to the heat, the use of verandahs, porches, loggias, and similar types of protection is admitted as being wise and very necessary. There are limits to their uses and advantages, however. I believe that they are often needlessly employed, particularly on the southern side, where they rob the rooms adjacent, not only of their cheerfulness, but also to a degree of their healthfulness.

One readily admits that other considerations such as the careful conservation of roof waters affects one's judgment in these matters, and the broad expanses of roof and verandah are very often necessarily so regarded as being a first consideration, particularly in dry districts.

Shade and Coolness.

Consideration should be given to the judicious planting and placing of suitable trees, not only as break-winds, but as the creators of shade and coolness, for in many circumstances this method is equally efficient and certainly less costly than many of the heavy verandahs erected.

The keeping of a house cool is certainly a complex question. The very general use of iron in South Australia, used in conjunction with other materials, is one of the chief factors against cool houses.

One of the greatest weaknesses in home building is the lack of care exercised in preventing the radiation of heat from roofs to ceilings. The old-fashioned lath and plaster ceilings, with all their faults, were certainly much better insulators than some of their successors, and with the use of comparatively thin sheet ceilings of to-day the use of some definite insulation is not only desirable but almost imperative.

One cannot help regarding the apparent indifference displayed in respect to so important a feature as this as being unnecessarily stoical.

The question of *cool homes* can be summed up in the following:—

Thick walls are excellent protection against the direct rays of the sun.

Ceilings should be lined with materials that insulate; or, failing that, have them packed with some suitable insulating material.

In the case of framed walls, line internally with a material with definite insulation value, or pack the framed walls with some insulating material.

Provide sufficient verandahs, porches and trees to protect the home from excessive direct heat.

Keep the sun off windows by means of external blinds or shutters.

Provide a sufficiency of well-placed windows to take advantage of cooling breezes or cool changes.

In respect to cold conditions, we do have some particularly cold weather, felt perhaps more because of the large difference in the extremes of summer and winter temperatures. We do not, however, suffer from the winters, for instance, experienced in Canada, where practically every household, however modest, regards some form of central heating as an integral part of the home.

Our conditions are such that in planning a home provision should be made for the general comfort of the household in the cold months of the year.

General Home Equipment.

The rapid growth of all forms of electrical aids to housekeeping has been most marked.

Let us hope that the day is not far distant when, by some means or other, the facilities enjoyed by town folk will be extended, so that it will be possible for you too to avail yourselves of their advantages.

Hot water services are one of the greatest assets to a well-run home. These can be provided to work with oil, coke, gas and electricity.

Water softeners render the housewife independent of the rain-water supply.

Household refrigeration is as great an advance on the ice-box as that very valuable acquisition is on the drip-safe.

The modern kitchen, equipped with its elevated stove, rustless steel or aluminium sink and drainer, well-planned and adequate cupboards, properly ventilated, is undoubtedly a joy to the housewife. Speaking of cupboards, let me impress on you the value, not only from the point of view of appearance but of efficiency, of cupboards fitted with doors having flush enamelled surfaces without mouldings of any kind. In place of shelving of solid wood cupboards for use as food storage can now be equipped with shelves of tinned wire mesh, easily removable and easily cleaned. The provision of a small alcove situated in or near the kitchen for mealing purposes is also a great asset.

In conclusion, let us give consideration to the house of the future, a little thought on which provides a most interesting study.

The advance of modern building science has been so rapid that one can look with confidence to the fact that great improvements and considerable change will take place in our homes, our methods, and our lives generally. Even to-day homes are being built entirely insulated from and unaffected by the heat or cold of the outside atmosphere. The whole of the air contained inside the home and breathed by the occupants can be washed, filtered free of all dust and germs, and its temperature controlled to any degree by a simple adjustment in any particular room.

Windows are being used for the admission of light only, and are being glazed with special glass, permitting the access of the valuable ultra-violet rays, otherwise cut off from persons inside a building.

Buildings are also being insulated against all forms of outside noises—a particularly necessary feature of apartment life in crowded and noisy areas.

These particular innovations are actual fact; although not common practice in Australia they are frequently availed of in the great cities of the world.

CONFERENCE OF WOMEN'S BRANCHES AT PINNAROO.

Mrs. J. Johnson presided over an excellent attendance of delegates from the Pinnaroo, Wilkawatt, Parrakie, and Parilla Well Branches at the Conference which was held under the auspices of the Parilla Well Branch, at Pinnaroo, on September 18th.

Mr. A. J. A. Koch (member of the Advisory Board), in the course of the opening address, expressed pleasure at seeing such a large attendance, which was evidence, he said, of the interest shown in the Women's Branches of the Bureau in the mallee areas.

No less than the farmers themselves, the womenfolk of the country were doing their share in steering the farm through these difficult days. Twenty-five to thirty years ago the town they now knew as Pinnaroo was only a maze of mallee scrub. To-day the country served by the railway from Tailem Bend to Pinnaroo carried 800 farmers and their families—wonderful progress in such a comparatively short space of time, and equally with the farmer, his wife had played her part in the pioneering stages of the settlement of the mallee. He congratulated the ladies on the wide range of subjects that they would discuss at their Conference, and felt sure that all would feel that the Conference had proved interesting and instructive.

It was resolved:—"That members of Women's Branches represented at the Conference do some form of charitable work to be forwarded to any desired institution."

To boil a ham that has become dry Mrs. Young, of the Pinnaroo Branch, advised that it should be first soaked in plenty of water for 24 hours, then placed in a boiler of fresh water, and boiled quickly without lifting the lid for 20 minutes or longer, according to the size of the ham. If large it should be left for three-quarters of an hour, or if exceptionally large one hour. Prepare plenty of bags, and place two in a washing trough or tub, put boiler on these, and then cover well with bags or old woollens, and leave until the following morning; the steam cooks the ham, and makes it soft and tender.

Delegates attended a combined meeting of the Men's Branches at which Mr. C. F. Anderson (Poultry Expert) delivered an address, "Poultry Keeping in the Mallee."

Miss E. Campbell, of the Education Department, spoke on the care and food value of milk.

Mrs. F. Atze, Pinnaroo, gave a demonstration of making a floral design, and the following papers were read and discussed:—

THE PIE MELON AND ITS USES.

[Miss Colwill, Parilla.]

Although the melon is not so valuable as most fruits, and does not compare with the peach, pear, and the apple as regards palatability, yet it has many things in its favour, and stands alone in its many uses for adding to other fruits.

The melon finds its favour in being insipid and tasteless. In these days when we all want to make everything go its furthest the melon again comes to our assistance in making jam, pickles and chutney, and making into pies. It is quite profitable to use the melon with other fruits without affecting the flavour of the desired fruit.

The melon, being tasteless, does not extract from the stronger flavoured fruits. When making jam or jelly, use when possible, the red-seeded melon; it is much better than other varieties. To have jam nice and clear and to set well, a good, fresh firm melon is best. Mostly when a melon of a few months' standing is used it becomes soft, and often is spongy in the centre. The jam then takes much longer to boil, and is tough, and generally has a cloudy appearance.

Cultivation.

The cultivation of all melons is similar. An open, exposed, warm situation should be chosen, deeply dug and well manured soil, and an ample supply of water during the time they are growing. They can be grown in any garden soil, but favour a light, rich sandy soil. Prior to planting, dig a hole 4ft. or 5ft. square and 18in. deep; mix the soil taken out with well-rotted manure, and return to the hole. Leave the surface in the shape of a saucer, so that it will retain the water applied to it. Sow the seeds directly into the ground; transplanted plants seldom grow. Plant several seeds in the hole, about 1in. below the surface, and cover with light soil. Quite probably, more seeds will germinate than are required. If so, pull up the weaker plants, leaving two or three to mature.

When the plants have made three or four leaves, hoe the ground and mulch it with manure, keeping it moist in the early stages of the plants, increasing the water as the plant develops. If particularly fine fruit is wanted, give liquid manure once a week. When the vine has made sufficient growth to cover the ground peg the runners down every yard or two to prevent the plant from becoming misplaced and spoilt through the wind blowing the runners about. This also helps in keeping the ground moist, because the runners are kept in place and the ground is shaded. Stop the main shoots at the fourth or fifth joint above the fruit to promote growth of the lateral branches. If the fruits are raised it prevents them from suffering through being on the damp ground. Keep the plants well watered while growing, otherwise the fruit will not be a success.

When the fruit begins to ripen, cut off the water supply, for little or none is then required. Sun and air will ripen the well-developed melon. When the foot stalk cracks away from the fruit it is then ready to cut, and if carefully packed away, will remain good for months. The melon—apart from its uses at this time of the year—provides abundance of green in the garden that would probably be dry soil, always giving a cool, refreshing appearance. Apart from the pie melon, the water melon, rock melon, and sweet melon are very useful. Most people grow them for their fine flavour. They make a very tempting and delicious dessert. Their light colours are very attractive.

Pie Melon Recipes.

1. *Melon and Lemon.*—6lbs. melon, 7lbs. sugar, 6 lemons, ¼lb. preserved ginger, 1½ teaspoons ground ginger, 1 teaspoon tartaric acid, 10 cups water. Method—Cut

melon and lemon into small pieces, add water and 2 cups of sugar. Stand all night; next day boil ¼ of an hour. Add other ingredients, and boil for 1½ hours, or longer if necessary.

2. *Melon and Orange.*—6lbs. melon, 6 oranges, 4lbs. sugar. Method—Cut melon into small dices and oranges into thin slices. Stand over-night; next day boil a few minutes; then add sugar. Boil until clear, and a little will set in a saucer when tested.

3. *Melon, Lemon and Orange.*—2lbs. melon, 2 oranges, 6 lemons, 4lbs. sugar, 7 cups water. Method—Cut melon into small dices, cut orange and lemon very fine; boil all without sugar for ½ an hour; add sugar, and boil about 1¼ hours.

4. *Melon and Passion Fruit.*—8lbs. melon cut into small squares, 6lbs. sugar, juice of 3 large lemons. Let sugar and melon stand over-night; next day add lemon juice; boil about 2 hours, or until melon is soft and clean. When nearly done add the juice of 18 passion fruit. When jam is done, take off the fire, stand for ¼ of an hour; then add the passion fruit seeds, stirring them well in. If the seeds are boiled in the jam they become hard and black.

5. *Melon and Pineapple.*—These make a good combination, allowing equal quantities of each fruit, and ¾lb. sugar to every pound of fruit (mixed). Method—Cut melon into squares, boil until tender, just sufficient water to cover them. When soft add the peeled pineapple, which has been minced, boil a few minutes; add sugar; boil fast for ¾ of an hour, or until fruits set when tested.

6. *Melon and Blackberry.*—Allow ½lb. blackberries to each 1lb. of melon, and ¾lb. sugar to each 1lb. of mixed fruit. Cut melon into small pieces, put fruit into pan with 1 cup of water to each 4lbs. of fruit. Simmer until soft, then rub through a sieve. Return pulp into pan with sugar; when the latter has dissolved boil fast for ¾ of an hour. Grated rind and juice of 1 lemon to every 3lbs. of fruit may be added. Blackberry jam may be added to melon if fresh blackberries are not obtainable, and make a very nice jam.

7. *Mock Ginger.*—1gall. of water over ¾lb. of lime; let stand until clear; strain through muslin. Method—Cut 12lbs. melon into small pieces, pour on lime water, and stand over-night; drain, and put into preserving pan. Add 1gall. of fresh water, 12lbs. sugar, 2lbs. preserved ginger, ½oz. citric acid, ½lb. whole ginger (bruised); boil gently for 6 hours.

8. *Melon and Quince.*—Cut 18lbs. melon into squares, 15lbs. quinces; cut into slices; and 21lbs. sugar. It is not necessary to peel quinces. Let melon and quinces stand over-night; add part of the sugar; next day boil for about ½ an hour. Add remainder of sugar; boil until a nice red colour, and will set when tested.

9. *Melon and Dried Apricot.*—6lbs. melon, 2lbs. dried apricots, 4½lbs. sugar. Method—Cut melon into small squares. Let stand over-night with sugar. Soak apricots in water (sufficient to cover them). Next day boil all together until melon is soft and clear. The jam will have the appearance of apricot jam.

10. *Melon and Raspberry.*—2lbs. melon, 3 lemons, 8 cups water, 7lbs. sugar, 1 tin raspberry jam. Method—Cut melon into small pieces, cut lemon thinly, add water and stand over-night. Next day boil until melon appears transparent; add sugar and berry jam, and boil until mixture will set.

11. *Melon Jelly.*—Cut 8lbs. melon into small pieces, leaving in the seeds and rind on; add 1½lbs. sugar, and stand all night. In another vessel cut 7 fresh lemons very fine; cover with 6 pints of cold water; stand all night. Next day mix together, and boil until soft; strain through cheese cloth, and to every pint of juice add 1lb. sugar. Boil gently for 2 hours.

12. *Melon Tart.*—Boil the melon until quite soft, then turn into a colander to drain. Add sugar to taste (this makes ample juice for the tart); add a pinch of citric or tartaric acid. Other flavouring for melon tarts which make a nice change when added to the cooked melon are the juice of a large lemon, ½doz. passion fruit,

or ½ cup of raspberry jam. Any one of these will take the insipid taste from the melon. Line a plate with a thin layer of pastry; add melon mixture and a thin layer of pastry on top. Bake in a fairly quick oven.

13. *Melon Chutney.*—Melon is excellent for chutney or pickles. 9lb. melon, 2½lbs. seeded raisins, 1lb. currants, 3ozs. garlic, 6ozs. dried ginger, 2½lbs. sugar, 3 dessertspoons chillies, ¼lb. salt, 4 quarts vinegar, ½ cup honey. Put the fruit and vegetables through the mincer; add other ingredients, and simmer until soft and thick.

14. *Melon Chutney.*—5lbs. melon, 3 large onions, 4 cups sugar, 4lbs. apples, ¼lb. bruised whole ginger, ¼ teaspoon cayenne pepper, 1 tablespoon each salt, cloves, and peppercorns, 1 teaspoon mixed spice, 3 pints vinegar. Method—Cut melon and onion into small pieces; put into preserving pan with cold water to cover; boil 10 minutes; strain off water; return vegetables to the pan with other ingredients; tie ginger in a muslin bag; boil apple before adding to other ingredients; boil all together for 1 hour, or until a desired consistency; bottle, and cork securely when cold.

15. *Melon Pickle.*—10lbs. melon, free from skin and seeds, 6 large onions. Cut into small pieces, put into bowl, sprinkle with salt; let stand over-night. In the morning strain off the brine through a colander, and add 4 pints vinegar, 1 cup each sugar and golden syrup, 1 teaspoon cayenne pepper, 1 tablespoon peppercorns tied in a bag, 1 dessertspoon tumeric, 1 teaspoon curry powder mixed with a little vinegar. Boil together for 10 minutes, then add the drained melon and onion, and boil until tender; then thicken with 1 tablespoon mustard, mixed with a little cold vinegar and 2 tablespoons flour. Add to the mixture, and boil for a few minutes.

MARKETING OF EGGS.

[Mrs. E. C. SLATER, Parilla Well.]

The time has come when eggs must be sent to market in the most attractive way. First of all, eggs must be perfectly fresh. An egg with an air-cell larger than sixpence is classed as stale, and would not be passed as fit for export. Eggs must be clean, and of a good shape. Dirty eggs and eggs of a bad shape are classed as rejects. In cool weather eggs must be gathered once a day; in hot weather three times. In hot weather I gather the eggs about 10 a.m., 2 p.m., and at feeding time, about 5 p.m. As a rule, very few hens lay after about 2 p.m. Before putting eggs away is the best time to stamp them, also to clean any that need it. To clean the eggs, hold the egg in the left hand with a dry rag, and use the damp rag with the right hand. Be careful not to shake the egg, or the air cell may be fractured. For some companies the eggs have to be graded. Eggs are packed and graded in layers of 2ozs. and over 1¾ozs., 1¾ozs., and underweights. This may seem a lot of trouble, but one soon becomes used to it, and it is satisfactory to know that the eggs sent to market are fit for export.

EARLY MORNING BREAKFASTS.

[Mrs. M. S. DAVIS, Parilla Well.]

Breakfast is always a problem, for it must be a quickly-prepared meal, as well as provide a good start for the day. First and foremost, the fire must be set the night before. This saves time in lighting, and the wood is well dried by the warmth of the stove before morning, thus giving the fire the best possible chance to burn. Secondly, it is not any trouble for the menfolk to put a match to it, and by the time the housewife is dressed the kettles are almost boiling.

We want to make as much variety as possible in our breakfasts, without taking up too much time. We must first decide what constitutes an ideal breakfast dish. A good breakfast dish is one that can be cooked quickly, or a cold stand-by that

has been prepared beforehand. The usual breakfast favourites, such as eggs cooked in different ways, bacon with fried bread, tomatoes, sausages, kidneys, or liver come under the heading of things that can be cooked quickly; while a cold stand-by may be one such as cold boiled ham, brawn, or any other cold joint. Breakfast also provides an excellent opportunity for using up odds and ends from the day before, and so preventing waste without letting the family realise that you are using up cold food that is left over.

All breakfasts mostly start with some cereal, such as semolina, oatmeal, wholemeal, crispies, &c., served with milk and sugar. Although the solid part of the breakfast may differ considerably, most people drink tea or coffee. Good coffee is as easy to make as tea, if one uses enough of it and never allows it to boil; this gives it a bitter taste. This recipe for making coffee is very simple and good:—To each person allow 1 dessertspoon of good coffee grounds and ½ a pint of boiling water. Heat a jug and put in the coffee, pour on quickly the required amount of boiling water, cover with saucer or lid, and stand it where it will keep hot. Leave for 5 minutes, then stir with wooden spoon, and stand another 5 minutes. Strain well, and serve with hot milk. The secret of success is to keep the jug of coffee hot all the time without letting it boil.

Some Breakfast Hints.

If bacon is salt, put in frying pan, cover with cold water, and bring to the boil; then pour away the water and fry the bacon in its own fat, if possible. Bacon is nicer if cooked quickly. Fried sliced apples are good with bacon for a change.

Toast should be made quickly or it will be tough—not crisp, as it should be. When made, it should stand upright to allow the steam to escape, and thus prevent it becoming sodden. If one has many slices to toast, place slices of bread in the stove, and they are then warm and toast more quickly.

Sausages should not be fried too quickly, or they will break. If sausages are too rich fried they are very nice boiled for 10 minutes in water.

Kidneys make a nice breakfast dish, but should not be allowed to curl. To prevent this, split open each kidney after removing the skin, stick a skewer through the opened kidney to keep it flat, and quickly fry in a little fat, cooking the cut side first. Serve underdone rather than overdone.

Scrambled eggs on toast are a favourite dish. Here is a tasty variation:—First melt 1 tablespoon of butter in the frying pan, then put in a little cold vegetable, or some chopped meat or ham. Beat the whites of the eggs first, then stir in the yolk with 1 tablespoon of warm water to each egg, salt and pepper to taste. Pour the eggs quickly on to the vegetables or meat that have been heated in the butter, keep turning it over with a knife for a few minutes until it is just set, not hard or tough.

As a change from the old way of having bacon and egg served together on a plate, spread a thick piece of toast or fried bread with chopped-up bacon or ham, then lay a poached or fried egg on top; sprinkle with grated cheese, if liked.

We then have the using of cold vegetables—"bubble and squeak." Bubble and squeak is made of left-over cold potatoes, cabbage, or any other vegetables. Heat a very little butter or fat in the frying pan, and put the cold vegetables in, and keep well stirred and mashed together until heated. Cold meat can be made to go a long way by cutting into thin pieces and dipping in a batter made of 1 cup self-raising flour, pepper and salt, and mixed with cold water. A little chopped parsley is an improvement. Make the same consistency as for pancakes. Dip pieces in the batter and fry in hot fat, not too quickly, but hot enough to brown them. These, eaten with sauce or an egg or bubble and squeak, are very nice.

Chops are very tasty for breakfast. They are made extra nice by beating up an egg, dipping them in it, and then rolling them in breadcrumbs. This could be done the night before, thus saving time in the morning. It is a good idea to put any left-over scraps of bread from the table in the stove to dry and then roll them. Kept in a jar or tin, they are always ready when needed.

Gravy is very important with a fry. To make good gravy, first drain fat from frying pan, leaving about 2 tablespoons of the fat in it; put this on the fire and then sprinkle in about the same amount of flour through the sifter. It is very important to sprinkle flour with sifter as it spreads evenly. Let it brown and cook well, but not burn. Have ready a cup of cold water, and as soon as taken off the fire stir in the cold water. Mix well in order not to leave any lumps, then add some hot water. Put back on the fire, season, and boil for a few minutes.

Lamb's fry is practically the quickest breakfast dish to fry, but if done this way will always be tender. Slice liver thinly, flat way of liver, thus giving nice large pieces; dip in plain flour, sprinkle with pepper and salt, and fry in hot fat just enough to brown, but fry quickly, then turn and fry the other side. Take from pan and put in a small saucepan. Make gravy and pour over liver, place the lid on and put in on the side of the stove to simmer for a few minutes. This makes it very nice indeed and very tender.

There are many dishes suitable for breakfast, and many small jobs which may be done the evening before that help considerably in getting the breakfast quickly—filling kettles, laying the cloth and putting down dishes and cutlery, cutting chops, bacon or liver, &c., but the main thing is to know the evening before what is for breakfast.

BISCUITS—PLAIN AND FANCY.

[MISS KATHLEEN SIMPSON, Parilla Well.]

Short Biscuits.—1 cup good dripping, 1 tablespoon vinegar, 2 cups sugar, 2 eggs, 1 sifterful flour, ½ teaspoon salt, 2 teaspoons cream tartar, 1 teaspoon soda, ½ cup milk (a little more if needed). Method—Melt dripping with vinegar, beat sugar with egg yolks, whip the white stiff, add milk and a few drops of essence, then flour sifted with salt, &c. Divide dough into three parts. With floured hands roll one part on baking board in a long roll. Take a sharp knife, dip in flour and cut roll into ¼in. slices. Place on greased slide and bake a nice brown. These biscuits can be iced and decorated or eaten plain.

Chocolate Cream Sandwich Biscuits.—7ozs. plain flour, 2 tablespoons each cornflour and icing sugar, ¼lb. butter, 2 tablespoons cocoa. Method—Beat butter until creamy, add sugar and beat well. Then beat in cornflour, and lastly stir in sifted flour. These biscuits should be put through a forcer.

Chocolate Filling.—2 tablespoons each butter, sugar and grated chocolate or cocoa. Beat until creamy. Allow to cool and firm before using.

Raspberry Cream Sandwich Biscuits.—Method—Make in same way as chocolate creams, but omit chocolate or cocoa in the biscuit mixture. Use raspberry cream filling made by beating 2 tablespoons of butter, 4 tablespoons icing sugar, and 1 tablespoon raspberry jam. Allow this mixture to cool and firm before using.

Forcer Biscuits.—1 cup each butter and sugar, 2½ cups flour, 2 eggs, 1 tablespoon each ground rice and maizena, 1 teaspoon cream tartar, ½ teaspoon carbonate soda. Method—Beat butter and sugar, add eggs (well beaten), then dry ingredients. Put into forcer and make into shapes as desired. Bake in a moderate oven.

Rosala Biscuits.—2 cups self-raising flour, ½ cup sugar, ¼lb. butter, 1 egg, icing sugar. Method—Mix all dry ingredients stiff with yolk of egg and little milk. Roll out very thin. Beat white to a stiff froth, then add icing sugar to make a firm paste. Spread over dough, sprinkle with cocoanut. Cut in fingers; bake 15 minutes.

Rolled Oat Biscuits.—¼lb. butter, 1 cup sugar, 3 cups rolled oats, 1 egg, 1 dessertspoon golden syrup, 1 teaspoon cream tartar, ½ teaspoon carbonate soda. Method—Melt butter, beat eggs and sugar together, then add butter, golden syrup, rising and oats. The mixture seems a bit dry, but it does not need any more moisture.

Put in little heaps on a greased tray. When cooked leave on tray for a few seconds to harden. If left too long they break up; in that case just warm them again.

Ginger Nuts.—1lb. flour, ½lb. treacle, ¼lb. dripping, 3ozs. sugar, 2 tablespoons milk, 1 teaspoon carbonate soda, 2 teaspoons ginger, 1 teaspoon mixed spice, and pinch of salt. Method—Melt treacle, dripping and sugar together, add milk and dry ingredients; knead well. Bake in a moderate oven.

Italian Biscuits.—1lb. flour, ½lb. each butter and sugar, 1 teaspoon nutmeg, 2 teaspoons cinnamon, ½ teaspoon carbonate soda, 1 teaspoon cream tartar, ½ cup milk. Method—Mix well together, roll out thin, bake in a brisk oven. Stick two together with raspberry jam. If wanted ornamental, put a tiny bit of icing on each.

Sao Biscuits.—Rub 2 large tablespoons butter into 2 cups plain flour with 1 teaspoon salt. Mix to a very stiff dough with milk. Roll out as thin as possible; cut into shapes, and prick with a fork. Bake in a very hot oven for a few minutes until slightly brown and crisp. They are nice with buttermilk instead of milk.

Cocoanut Biscuits.—Mix together 4ozs. flour and cornflour. Rub into this 3ozs. butter. Add 4ozs. castor sugar, 3ozs. desiccated cocoanut and 1 teaspoon baking powder. Mix with 2 eggs, roll out, cut into shapes with a fancy cutter, and bake in a moderate oven.

Jew's Biscuits.—1lb. flour, ½lb. each butter and sugar, 2 eggs, 1 teaspoon cream tartar, and ½ teaspoon carbonate soda. Roll out on tray, polish over with egg, and sprinkle on sugar and cinnamon and sliced almonds. Cut into squares.

Finger Biscuits.—Cream ¼lb. butter with 2ozs. sugar, add the yolk of egg and 1 tablespoon water (beaten together first), add ½lb. self-raising flour (or plain flour and 1 big teaspoon baking powder); blend into stiff lump, and roll out thin on floured board. *Icing.*—5 large tablespoons rolled icing sugar, 1 white of egg, 3 tablespoons cocoanut. Cut biscuits into fingers, spread with icing mixture, and sprinkle with cocoanut or chopped almonds. Bake about 15 minutes in moderate oven.

BALHANNAH.

July 17th.—Attendance, 19.

Gardening.—Mrs. Botroff read the following paper:—"An ornamental garden should be divided into walks, lawns, rockeries, and beds. Individuality can be expressed in a garden and the house and surroundings should reflect the tastes of the owner. In laying out a garden, natural features should be taken advantage of as much as possible. Where there is a good view or outlook, an opening should be left so that it is not obscured. Undesirable surrundings can be hidden by a trellis, hedge, or trees or a bush house. Irregularities in the ground can be taken advantage of to introduce a few steps and curves in the paths. Banks can be grassed and planted with bulbs, or they may be covered with some Wichuriana roses, which delight in such situations. These roses are also excellent coverings for old tree tumps and roots. Arches for roses can be easily made of rough timber; if planted with some of the more vigorous climbing varieties, they are soon covered, and form a delightful feature in a garden. There are various creepers that can be grown over frameworks, to form nice shady walks. The provision of breakwinds for sheltering the flower garden from cold or hot winds is important. Plants will not thrive without adequate protection. Another method is to plant hedges and trees, but they rob the ground of moisture and nutriment. For raising seedlings, shallow boxes make a very good substitute; these should have a number of holes drilled in the sides and bottoms, and be a quarter filled with crocks, charcoal, or other good drainage material. Only about 3in. or 4in. of surface soil is necessary. A good soil for sowing seeds in consists of equal parts of sandy loam and leaf mould, with a mixture of rough water-washed sand. In preparing the soil, press it firmly, then sift fine soil on the top and make it quite even, and give a good watering some hours before sowing the seed. If the seeds are very small no covering will be required; just press them equally with a flat piece of board into the damp soil. If the soil has been properly soaked previous to sowing, probably no water will be required until the seeds germinate, but as soon as the soil shows signs of drying, it should be watered with a very fine spray, so that the surface will not be disturbed and the seeds washed away. Some seedlings are hardier than others. It is advisable to make a couple of sowings of each packet, with a week's interval; the second sowing often proves a success when the first has failed. Heavy rains do a lot of damage to young seeds. Light wooden frames covered with wire-netting, over which hessian or cotton shading is stretched, is a great help; whatever shade is used should obstruct as little light and air as possible. Choose a moist, calm, dull day for planting out seedlings. The soil should be damp and the holes not opened until the plants are ready to go in the ground.

Vegetable Gardening.—The best soil is a deep light, friable loam, but any ordinary soil can be made into a good garden with care and attention. One of the main things is to keep the ground free from weeds. The hoe should be kept at work to kill the weeds and maintain a loose surface. Very light soils are best manured with cow manure; horse manure is best for heavier soils. Unless the ground is very sandy and naturally drained it is advisable to artificially drain a garden. In ordinary digging thoroughly turn the soil over and except in very shallow soils the spade should be used to its full depth. Keep a small trench open when digging and all surface weeds can be put into this and buried. Excellent long-lasting manures can be used in conjunction with wood ashes and well-rotted stable manure. They contain little or no potash, and as this element is deficient in most soils, a dressing of some other manure containing potash is adviable. All seeds do not take the same time to germinate, nor grow with equal strength. In light, dry soil fairly deep sowing is advisable, while in heavier soils and cooler situations shallow sowings are preferable. Such large seeds as Peas and Beans may be sown from 1in. to 2ins. deep. Beet, Cucumbers, Melons, Pumpkins, and Marrows ½in. to 1in.; while the smaller seeds which do not require transplanting should always be planted in rows, so that they can be easily weeded and cultivated. Transplanting should be done in moist, cloudy weather. Give the seed-bed a good soaking, then lift the plants with as much soil as possible, taking care not to damage the roots. They should then be planted in rows the same depth as they grew in the seed-bed—using a pointed stick to make the holes—then firmly press the soil around the roots. Water them well, and if the weather is very hot provide shade. Use a line for planting the garden, so that the rows will be straight. Water Melons and Pie Melons should not be planted anywhere near each other, because of the danger of cross-fertilisation. The best way to grow Pumpkins, &c., is not to plant until the spring is advanced; the seeds will not germinate in cold ground. Have the soil well manured, and plant the seeds about 2ft. apart in rows, and when big enough bank up the earth about 3ft. each side away from the pumpkins so that when watering the water will not waste. They need plenty of water and some liquid manure." (Secretary, Miss D. Spoehr.)

MILLICENT (Average annual rainfall, 29.76in.).
June 15th.—Attendance, 10.

GARDENING HINTS (*Mrs. Bryant*).—"Gardening is an interesting and healthy occupation for either man or woman. The soil must be well worked and weeds kept down, digging in occasionally some lime and later manure—do not use both together. Lime is a splendid vermin destroyer. Sandy soils require more manure than heavy soil. After planting out rows of either vegetable or flower seedlings keep the soil loose between the rows. Chrysanthemums do well in sandy soil with old stable manure dug in and allowed to remain some time before planting. Plant out one root with one stem in August about 3ft. apart, and by November top them to keep the growth down. Put down stakes to tie them to—they are very brittle and break easily. If large blooms are wanted bud them as soon as the buds show up, leaving one bud on each strong stem. They will then flower through autumn and early winter."

DAHLIAS (*Mrs. J. Jenson*).—"The dahlia first originated from Central and South America where in its natural state it is a scraggly bush 6ft. or 7ft. high bearing single blooms of a purplish colour. They were named after Dr. Dahl, a Danish botanist. Dahlias are a good late summer or early autumn flower, and with proper care and attention bloom for 2 or 3 months. There are many varieties such as Cactus, Decorative, Pompone, Collarette, Paeony, &c. The Cactus type has long narrow petals which are twisted, curled, and pointed, while the Decorative is the very largest of all, holding its beautiful flowers on stiff stems well above the foliage. When well grown some of the flowers are almost a foot across and make a show in any garden. Pompone dahlias are like a honeycomb ball, and last the longest when picked. Collarette dahlias are one of the most popular. The flowers are large and single, with a fringe of small thin petails surrounding the centre, the fringe being a different colour from the petals. The Paeonys have very large flowers with petals loosely arranged, they are fine for cutting. The best time for planting in this district is the end of November or early in December, then they will not be flowering in the hottest part of summer. Seeds must be sown in September, they will then flower the first season. Sow the seeds in a plot and when about 5in. or 6in. high plant out. Seedling dahlias change colour until 3 years old. When deciding where to plant, choose a place if possible where they will be sheltered from wind and have a fair amount of sun. Where the ground is black and heavy plenty of sand and manure are necessary. Where the soil is sandy all that is necessary is manure. Spread the sand over the garden, cover with manure and dig fairly deep, turning it well over. After digging, rake well to break all lumps. If the bulbs are very large divide them, this must not be done until they have "shot," as they are likely to die if cut up without shoots. Plant in rows 3ft. apart either way and about twice their own depth, this gives them plenty of cover, food, and strength to send up and hold flowers and foliage. Bulbs planted too near the surface become sunburnt and are ruined. If the ground is dry when planted, give a good watering. Water is one of the main things for the growth of the bulbs. When the bushes are about 2½ft. to 3ft. high, prune them back. If large flowers are wanted take out all the side shoots and leave only the main ones, but if a lot of flowers are needed take out main ones and leave the others. These grow out and make them more bushy. When finished flowering, if cut down to within a foot of the roots they will flower again in a few weeks. After they have done flowering dig up and put away where frost will not hurt them."

THE GROWING OF DELPHINIUMS (*Miss K. Hutchesson*).—"No plants are more beautiful in the garden than Blue Delphiniums. They are one of the most popular as well as beautiful perennial plants for the garden and indoors. The best results will be obtained by planting the one-year or two-year crowns. Larger and stronger plants will be obtained from the two-year crowns. For the planting of these flowers a rich deep loam to which a liberal supply of cow manure or leaf mould is worked in with a sprinkling of superphosphate or bonedust gives excellent results. Best results will be obtained if planted where they will only get the morning sun, but they also do well if planted in the open. Watch the Delphinium plants for pests, especially snails and slugs. To prevent them, frequently dust the plants with lime. By covering

coarse sand or scattering shell grit over the plants that are awakening from their rest a protection from slugs will also be given. It is not necessary to lift or divide these clumps every year.'' (Secretary, Mrs. Hutchesson.)

MUNDALLA (Average annual rainfall, 19.26in.).

June 20th.—Attendance, 15.

CUTTING OUT GARMENTS.—Miss Fisher first illustrated, by means of a blackboard and model, the methods of measuring and cutting out, and then read the following paper:—''Every girl and woman possesses a personality, but this personality is not expressed to the best advantage when one does not take a certain pride in the matter of clothes. There are many who say they cannot afford to dress well. If personality rests on buying Paris models, then it is quite true that many may not be able to afford the expense of clothing. The two essential points to remember in dressmaking are accuracy and neatness. Accuracy in measurements, cut, and fit; neatness in making, finishing and pressing. Each warehouse and shop stocks sizes to fit a normal woman's figure, therefore women, who are under and above those sizes, find it more satisfactory to make their own clothes, it is also more saving. The wearing of different underclothes gives a decided distinction. If making a frock for anyone, point out to the lady that so far as possible, it is better to wear underclothes of the same thickness when being measured as she will be wearing when she is to try on the frock. If a measurement is taken over silk underwear and the ''try on'' is made over woollens, the garment is apt to appear tight, or if tried on over silk, it may appear a little loose. When measuring around the waist, bust, hips, and armholes, the tape should not be pulled too tightly, but be just firm enough so that a finger can be placed underneath the tape between the figure and the tape measure itself. Also, take notice whether the neck be short and thick, or long and thin, bcause a short thick neck needs a narrow collar, and a long neck a wider one to take off the effect of the length. It is just as important to be able to select a design from a fashion journal as it is to know how to choose material for the garment desired. No fashion paper can be an absolute guide as to design. It can help by suggesting and giving ideas. If you like a frock, but are afraid it may be unbecoming, try to think how the design may be modified and adapted to suit you—perhaps the slightest change will make all the difference. Do not imagine that to be smartly dressed it is necessary to make an exact copy of a design. The designs are there to give ideas to represent the fashions. The correct and incorrect way to lay out material: This may not convey very much, but it really means saving pounds in the cost of materials that are purchased when making garments. The way that most people judge what quantity of material they intend buying for their dress is by taking their length and saying, 'I will want twice as much and about ¾yd. for sleeves.' The first and most important thing to be taken into consideration is the width of the material. All materials, whether they be linen, fuji, crepe de chine, or woollens 54in. material, should be opened flat out, and the pattern set on and marked carefully with chalk before attempting to cut into the material. Before cutting see that the patterns are pinned carefully and that they are smoothly placed on the material Always keep the material flat on the table while pinning. When cutting out, hold the scissors firmly in the right hand to make long cuts. Never lift the material from the table while cutting. Care must be taken to have meeting exactly all waistlines, length of skirt, and sleeve, neck, armholes, and shoulder lines of bodice and blouse. The important thing to remember when binding is that all binding must be cut on the cross or on the bias. A straight binding never lies flat. When making garments of velvet, always cut so that the pile runs the one way. Velvet or velveteens must never be pressed flat on the table with an iron, but the seams held at each end and passed over the iron. If a mistake has been made by not testing a small piece of material by damping first and thereby causing the portion of the garments to shrink where it has been pressed, the whole garment will have to be damped and pressed to correspond. Shiny spots on material can be removed by steaming. If a seam is at all puckered, get someone to hold each end of the seam while the iron is passed firmly backwards and forwards along the centre of the seam, until it is quite smooth.'' (Secretary, Miss M. Scown.)

TAPLAN.

June 25th.

THE CARE OF INCUBATOR CHICKENS.—Paper read by Mrs. P. Flynn:—''This is a very interesting hobby for any person who has a little time to spare; and although not so profitable as it used to be, there is still money to be made from good laying hens. First, our locality must be considered and as we are too far from the City to raise the table birds, we must turn our attention to the laying strains. The White Leghorn is

the best breed for eggs. To hatch any quantity of chickens, an incubator is necessary. Start the machine in June and run it until September, then stop until early February. The chickens hatched in February, March and April do very well; the days are warm and the nights are not very cold. They have every chance to thrive well, and start laying early in spring; by doing this you can save at least 2 months' feed, *i.e.*, by not hatching late in summer. I put water in the trays right from the first day, and put fresh water in a few days before the eggs are expected to hatch. Be careful not to chill the chicks when removing them from the incubator. Take a basket or small box, put chicks in and cover with a towel, put them in a brooder. If a heated brooder is not available, then a little more trouble must be taken for the first few days. Take a flat box about 6in. deep and 2ft. long for about 50 chicks, put clean fine sand in bottom, put in the chicks and, if a nice sunny day, put them in the sun. They do not require any food until they are a day old or more. It is very easy to tell when the little chicks are cold, they all huddle together. It is advisable then to cover them with an old flannel then after a while they will come out looking for feed. See that you have a wire netting frame to cover the top of the box to keep them safe from birds and cats. To put away the chicks for the night, have another box, a deeper one this time. Cover the bottom 3 or 4 inches deep with chaff, put in the chicks and cover with flannel, put the flannel down in the middle so that it will rest on the chickens and keep them warm. Put the box inside for the night. These hints are only for very young chicks. When they are a week old, they can be put in a run that is proof against birds, and a simple brooder made for them. Take a kerosene case, lay it on its side, have a false top inserted with the back of it half way to the bottom. This forms a slanting roof, strips of flannel should be hanging down connected to the false top, a stone jar filled with hot water and wrapped in flannel, should be inserted every night and morning if the weather is cold. A few points on feeding, give a little milk or water, No. 1 chicks food or finely cracked grain and a little oatmeal mixed for the first week, after that cracked grain, and dry bran; and if they will eat it, lettuce and a little meat liver is very good. Scraps from the table can also be fed. See that they do not get wet tramping in the water. A good plan is to take a jam tin and make a small hole with a nail, a quarter of an inch from the top, fill tin with water, clap a saucer on top and turn it up side down, this will fill the saucer with water up to the nail hole, and keep the chicks from tramping in the water. It is best to tie the tin down as the chicks grow older. Keep all yards clean and keep water in shady places. Do not overcrowd and by attending to these simple rules, you should have no difficulty in rearing chickens.''

CARE OF THE HAIR AND FEET.—Paper read by Miss R. Gogler: ''*The Hair*· Something in the dry air of the mallee districts, added perhaps to neglect, soon causes the hair to lose its shine and to become hard to dress. A few minutes devoted nightly to its care, or as often as can be managed, will work wonders. Sometimes people exclaim with a worried look, ''My hair is falling out dreadfully. What shall I do?'' Really, this happens every autumn in order to make room for new growth. A good deal depends on one's general health. If one is run down, the loss of hair will be greater. Brushing and massage for 5 minutes every night helps greatly. This exercises the scalp and keeps the oil glands functioning properly. A sun bath should be taken as often as possible. Run the fingers upwards through the hair to allow light and air to reach the roots. The majority of cases of falling hair is due to infection of the scalp with dandruff. This is a serious trouble caused by the enlargement of glands to which the hair is attached and a consequent flow of liquid from these glands builds up horny scales which cover the skin with a thick layer of dandruff. It affects the normal blood circulation and compresses the roots of the hair, which means that, as the roots are not getting sufficient nourishment, they shrink and finally die and fall out. To remove the oily scales, apply very warm olive oil to the scalp at least once a week and cover the head with a towel to prevent soiling the pillow case. This causes the head to become hot and the oil will sink deeper into the roots of the hair. A soft soap (which contains no alkali or resin) or coal tar soap makes the best shampoo. Wet the hair with warm water and rub soap into the scalp; leave on for 10 to 15 minutes rubbing all the time, then rinse thoroughly in cool water. The scalp should be dried quickly and rubbed briskly with a rough towel. If the hair is too dry, it should be washed only once in 3 or 4 weeks and olive oil rubbed into the scalp after the shampoo to keep the scalp nourished. Brilliantine dressing has the double advantage of adding oil to the scalp and giving a brilliant shine to dull hair. For those whose fair hair is darkening, the only remedy is bleaching, but this is not advisable as the new hair growing will be darker than the old, and the effect rather patchy. Frequent brushing and massaging the scalp with a rotary movement of the fingers gives a brilliant gloss. The juice of half a lemon added to the last rinse helps to keep the hair fair.

The Feet: After a day of standing on the feet, one feels glad to sit down and give them a rest. When sitting mending or reading, have a bowl and a kettle of boiling water beside you. Add bicarb. soda or salt to some water and soak the feet until the water is cold. Dry thoroughly, then massage upwards from the toes with an embrocation of equal parts of olive oil and methylated spirits. If the feet are tender or perspire excessively, rub them with spirit or liquid witch hazel. Dust the feet and the insides of the shoes with boracic acid. Shoes should be roomy and well fitting with medium heels and a well-supported arch. The best cut of shoe for those with troublesome feet is one in which the inside is cut almost straight from the instep to the toe, just curving slightly towards the toe. This gives the toes room to rest in their natural position. Continual wearing of slippers is most injurious, it allows the feet to sprawl and causes the arch to drop. It often is a relief to change the shoes several times a day, and change stockings frequently too. For excessive perspiration, regular soaking in warm water to which a handful of common salt and 2 tablespoons of washing soda have been dissolved, relieves them. Rinse with cold water after soaking for 10 minutes and rub common salt into the feet and ankles. Dry and rub with eucalyptus or methylated spirits. Iodex or Rexona are splendid for rubbing. There is a good exercise to strengthen the muscles of the feet and ankles. Sit on a comfortable chair and extend the right leg. Stretch the foot right out, then turn the toes alternately up and down as hard as possible. Then twist the foot round in circles, making the circles as large as possible. Twist them both ways, then repeat with the left leg. Another is to stand with feet together, and practise heel raising, moving the heels as far from the ground as you can. This gives the arch of the foot exercise.''

WARCOWIE (Average annual rainfall, 12.31in.).

June 28th.—Attendance: 11.

HOUSEHOLD HINTS.—(Mrs. E. Jarvis).—Always keep turpentine on hand; it is a splendid remedy for burns, and, if mixed with flour, a first rate remedy for corns, Boot polish that has become hard can be softened if a few drops of turps are added; also add a few drops to the stove polish—it gives a brilliant polish. To get rid of cockroaches, sprinkle powdered borax about all cracks and corners; they will soon disappear. Coffee or tea stains can be removed if put into water to which a little kerosene has been added. To preserve the brilliancy of white-handled knives, give them an occasional rub with the juice of a lemon. To sharpen scissors, take a bottle and work the scissors along the neck as if to cut it; repeat this about a dozen times. Mint sauce is improved by putting 2 tablespoons of boiling water over the mint and sugar 10 minutes before adding the vinegar. If a layer of white sugar is placed in the bottom of a biscuit tin the biscuits will keep fresh and crisp for months, even though the tin is not air-tight. To whip cream during hot weather, add as much cornflour as will cover a 2s. piece to ½ pint of cream. 1 teaspoon of cold water added to the white of an egg before whipping will increase the quantity Before roasting meat, sprinkle flour over it; the gravy will then be a rich brown. Add a little vinegar to the water in which meat is stewed or boiled; it will make tough meat tender. Add 1 cup of thick sour milk to the water to be used for mixing bread; it will prevent it from becoming ropey during summer. (Mrs. E. Sanders).—Tablecloths are inclined to tear at the corners because of the pulling required to get them into shape again. A small piece of linen sewn at the edge of the cloth at each corner will strengthen them considerably. To darn linen quickly, neatly tack a piece of muslin underneath the worn or torn part; then, using a sewing machine, darn backwards and forwards, keeping the lines of stitching straight and even. Trim off the muslin underneath, and when the article has been laundered the darn will hardly show. Windows and mirrors can be cleaned with thin cold starch, which is wiped off with a soft cloth after being allowed to dry thoroughly. Use thick boiled starch to paste covers on jam jars. Do not put pepper into rissoles or fritters to be fried, as it will break them up. Put a few seedless raisins in the breakfast porridge; it improves the flavour. Raspberry jam being very scarce, it is a very good plan to take 1 tin of dark plum and mix with 1 tin of raspberry. Avoid making jam of any sort in wet weather; it will not keep long, and tends to mould. It is often found that a custard will go watery. If it is a baked custard it is caused by the oven being too hot, and, if boiled, by using too much sugar. To rid a place of cockroaches, scoop out half a potato and fill with borax; place where the cockroaches are, and they will all disappear. A pen nib will not become rusty while not in use if it is stuck in a raw potato. A boiled potato used frequently instead of soap will keep the hands soft and white. If fat becomes burnt while frying,

drop a few pieces of raw potato into it and leave for a minute or so, after which all traces of burning will have disappeared. When windows are difficult to open, rub the cords with soft soap, and the sashes will run smoothly. Fat will not splutter while frying if a little flour is sprinkled into it before the cold food is put in. When poaching eggs, add a small piece of butter to the water to prevent the eggs from sticking to the pan. If an aluminium vessel is burnt it can easily be cleaned by boiling an onion in it. Left-over mustard will keep fresh if covered with water; pour the water off before using. (Secretary, Mrs. A. Crossman.)

WASLEYS.

July 5th.—Attendance, 29.

Rose Culture.—Paper read by Mrs. J. Hancock:—"There are different types of roses, standard, dwarf, and climbing. Standard roses are best grown where small annuals are to be planted. The dwarfs are best in a bed to themselves. Dwarf roses give best results, the wind does not bruise them so much, being lower and firmer, and I get the best and most blooms from these bushes. June is the best time to secure plants. Prepare the ground, digging it all over, and then take out holes to a depth of 12in. to 18in., and loosen the bottom soil with a fork. In new soil, manure is not necessary, but with soil that has been used for garden purposes put manure in the bottom soil and dig it in well, seeing that the roots of the roses do not come in contact with the manure. Then fill up with top soil, allowing about 9in. open to plant the rose trees. Standard roses should be planted about 9in. deep, and for dwarfs the soil should come to where it has been budded or close up to the first limbs. When planting see that the roots are spread out evenly before filling in the hole. Standards need a stake alongside to keep them in position, then firm the soil and give a good watering. Start pruning the first week in July, if pruned before, the bushes shoot too early and frosts very often nip them. Prune the poor growers hard and the vigorous grower not so much. Prune back to about 4 buds on the strong growing roses and perhaps 2 or 3 buds on the poor grower, seeing that the top buds point outwards. Keep the centre of the bush open by cutting spindly branches out and branches that cross over. When the roses commence to shoot, rub buds off pointing inwards, they fill up the bush and are of no use. About September apply a mulch of decayed manure to retain the moisture. If wanting show blooms, disbud to make better blooms, perhaps leaving one or two on stem. Sometimes in spring, when buds are forming, green aphis attacks them. Spray with a solution of soap suds and black leaf 40, which quickly kills them. After the spring flowering is over clean up the bushes by cutting back to a bud pointing outwards. I never let my roses want for water and have flowers continually throughout summer. Sprinkling is no good, let the hose run steadily for some hours, a good soaking lasts for several weeks. About March I give a good watering and then apply liquid manure to get the autumn flowers which I think are the best all throughout the year. Do not apply liquid manure without watering the roses first, it has a tendency to burn them; about ½gall. to each rose. Roses will not give best results if you leave the dead flowers on and sometimes go to seed. Also keep briars cut back at the bottom, if any should appear dig down with a spade and cut back as far as possible. If some of the roses are poor growers and do not give the best of flowers, it is just as well to have a good sort budded on them. Time to bud is December, and water well after budding to send the sap flowing. If needing more bushes of the best roses, success is often possible by cuttings taken from them and inserted in soil to two-thirds of length of cutting. The best time to do this is April or May, and water well. A few roses that are well worth a place in any garden:—Firstly Golden Emblem, one of the best yellow roses grown; Hadley, a red, very sweetly scented; Madam Abel Chatenay, a pretty pink; Mrs. Herbert Stevens, a constantly flowering white rose; Madam Edward Herriot, a tangerine; Shot Silk, shaded pinks; and Edward Mawley. Lorraine Lee is a pink, flowers a good deal in winter and needs pruning in March, and a wonderful grower, and flowers when roses are scarce."

A paper on "The Garden" was read by Miss A. Buckby, and Miss D. Sanders spoke on "Soap Making." (Secretary, Miss J. Braun.)

WIRRILLA, April 5th.

BREAKFAST DISHES.—By Mrs. W. R. Woods:—*Devilled Meat*: Put in a small frying pan 1 good dessert spoon butter, 1 teaspoon curry powder, 1 dessert spoon vinegar, pepper, salt, a little cayenne to taste, grate of nutmeg, also a little tomato sauce if liked. Cut slices of cold meat and simmer very gently in the mixture, turning once. The meat should only heat, not cook or brown, or it becomes tough. Serve on hot buttered toast. A good breakfast or luncheon dish for a small family. *Kidney Savoury*: Remove all fat and skin from 3 kidneys, chop them fine. Put small pieces of butter in saucepan, when hot, put in 1 teaspoon of chopped shallots and cook for 3 minutes, taking care not to let shallots brown. Then add the chopped kidneys and cook 5 minutes, sprinkle in about ½ teaspoon of flour, season them. Moisten with 2 tablespoons of good gravy, cook for 2 minutes longer. Serve on buttered toast, sprinkle with chopped parsley. *Crumpets*: Break 2 eggs into a basin. Beat slightly and add 2 teaspoons sugar. Sift ½lb. S.R. flour in another basin and pour in eggs to make a light dough (a little milk may be needed). Work quickly, roll to ½in. thick, cut into rounds. Prick with a fork, bake in hot oven for about 10 minutes, Tear open and butter while hot. Serve at once. *Tasty Dish made from Cold Meat*: Cut the cold meat very small, add 1 onion also cut small, pepper and salt to taste, just cover with water and stew gently for about three-quarters of an hour. Thicken with a little flour, have ready some slices of toast well buttered and heap on top of toast. *Another Cold Meat Recipe*: Mince the cold meat, season with pepper and salt, and grated nutmeg, moisten with water. Tomatoes added are an improvement. If adding tomatoes do not use too much water, as it must not be too wet. Pile on hot buttered toast. *To Use Stale Bread*: Cut 4 fairly thick slices of bread, dip lightly into mixture made up of 1 egg well beaten, ½ cupful milk, 1 pinch each salt and pepper. Fry in dripping until nicely browned, serve with fried bacon. *Tomato Toast*: Chop up a little bacon and put into a small saucepan to cook with a small piece of butter for a few minutes. Then add 2 or 3 tomatoes which have been skinned and cut up, and a little pepper. When tomatoes are well cooked break in 2 eggs and stir well. When thick enough put on the pieces of buttered toast. *Creamed Sausages*: Partly boil the sausages for 10 minutes, put them into cold water and bring to boil and boil 10 minutes. Then skin the sausages. Bring ½ pint of milk (with ½oz. butter dissolved in it) to a boil and thicken with cornflour. Remove from fire and season to taste with tomato sauce. Cut sausages into dice and add to the mixture. Pour over buttered toast and serve hot. *Nest Eggs*: 1½lbs. mashed potatoes, 2 tablespoons milk, 2ozs. butter, salt and pepper and eggs. Make the potatoes very hot, add butter, milk, and seasoning. Form into round shape with spoon on hot baking dish. Break an egg into each and bake in a hot oven until set. Serve hot. *Omelette*: Separate the yolks of two or three eggs from the whites. Beat the yolks with a little salt and pepper, add 1 tablespoon S.R. flour, 2 tablespoons cream or milk and a little chopped parsley. Beat whites separately and mix all together, have frying pan ready with boiling butter, pour in the mixture. Cook over a slow fire. When set and a light brown, roll over like a pancake and serve hot. Before cooking milk or eggs (omelettes and pancakes in particular) scour the pan with salt and rinse with hot water to prevent burning. See that the omelette pan is thoroughly dry before putting in the batter.

SMALL CAKES AND BISCUITS.—Meeting held June 7th. Recipes supplied by Mrs. A. Evans:—*Peach Cakes*: 6ozs. each butter, flour, and sugar, ½ teaspoon baking powder, 5 drops essence pineapple, 2 eggs. Bake in hot buttered gem scone trays and paint with carmine diluted in water and roll in castor sugar. *Plain Biscuits*: 3 cups S.R. flour, 1 cup each sugar and butter, 2 eggs, 4 tablespoons milk. Beat sugar and butter to a cream, add eggs one at a time and beat well, then the milk and lastly flour. *Queen Cakes*: 1lb. flour, ½lb. butter, 1 teaspoon baking powder, ½lb. sugar, ½ cup cream, 3 eggs, 1 cup currants. Beat butter and sugar to a cream, add eggs one by one, then add cream and currants and enough milk to make cake mixture. *Lunch Buns*: 3 cups S.R. flour, 1 cup each sugar and dripping, 2 eggs. Beat sugar and dripping to a cream, add eggs and beat well, add 4 tablespoons milk and sultanas, roll in balls and dip in sugar. Bake in moderate oven. (Secretary, Mrs. W. Jones.)

THE ICING AND DECORATING OF CAKES.

[By Mrs. P. E. C. DANIEL, Warramboo.]

(*Paper read at the Conference of Eyre's Peninsula Branches, at Kyancutta, on September 7th.*)

The decorating of a cake is just as important as the baking, and a plain cake can be made into an elaborate affair with a little time and patience, and many a cake which looks a failure when it comes out of the oven is quite unrecognisable after the icing process.

One of the most important points is the mixing of the icing. For sponges, I prefer mixing with hot water and a little butter to prevent cracking, and for flavouring, vanilla is used mostly. The icing is smoothed off with a knife dipped in hot water. Then if a pump is available it is quite a simple matter to make a neat edging around the cake, and perhaps a few other decorations, such as cocoanut or nonpariels in the centre.

The fillings add to the attraction of a sponge. With children jelly filling is most popular. The jelly should be just set, but not hard, and mashed with a fork before it is put in the cake. Then it will stick well. Whipped cream is another easy filling.

There are the other type of cakes for celebrating weddings, birthdays, and Christmas, etc. The correct procedure is to have almond paste for the first coating. This consists of ground almonds and icing or castor sugar, ratafia and vanilla flavourings, and is mixed with eggs, yolk and all. It can be purchased ready mixed from the confectioners. To make the paste stick, it is necessary to brush the cake over with white of egg before applying. This coating is left for several days to harden. The mixing of the plain icing is done with white of egg, and must be stiff enough to hang from the knife if held up. The cake will need one or two coatings of plain icing, this depends on the importance of the occasion, or the length of time the cake is to be kept, as the grease from the cake is apt to come through in spots if the icing is not thick enough. Each coat as it is applied must be smoothed over with a knife dipped in hot water. If the final coating is to be white, a little washing blue is added.

When the final coating is perfectly dry decorating is the next step. The icing must be mixed carefully, for if it is not stiff enough it will fall out of shape. The design should be pencilled on the cake first, and with the help of a bottle of silver cachous an attractive cake can be turned out. Bought ornaments look very nice, but are rather too expensive for ordinary occasions.

A fancy top ornament is necessary for a wedding cake. These will cost anything from 5s. upwards. When using pillars it is necessary to have white cardboard under each storey. Pillars are rather an expensive item, but nice ones can be made by sawing a broom handle into the desired lengths and covering with white or silver paper, or for a birthday cake they look very nice pink.

Decorating cakes is a very fascinating pastime, but requires a fair amount of time and a steady hand.

BISCUIT COMPETITION RECIPES.—One member's exhibit was made with dripping, no butter being used in any of the varieties, the biscuits were sampled and proved to be excellent, these biscuits will keep as well as those made with butter. Following are some of the recipes, the first 6 being the first prize:—*Honey Biscuits*: 1lb. sugar, 1 cup honey, 3 eggs, 2 teaspoons c. soda, 1 teaspoon ground ginger, cinnamon and a little spice, about 5 cups flour. Roll in balls, place nut on top and bake. *Cocoanut Crispies*: 2 cups rolled oats, 2 tablespoons golden syrup, 1 cup flour, 6ozs. butter, 1 cup each sugar and cocoanut, small teaspoon vanilla, 1 teaspoon carb. soda in 3 tablespoons of hot water. Mix butter and sugar, add syrup then soda in hot water, rolled oats, cocoanut, and flour. Drop on tray with teaspoon and bake in slow oven. *Walnut Fingers*: ¼lb. butter, 2ozs. sugar, ½lb. flour, 1 teaspoon c. tartar, ½ c. soda, yolk of 1 egg, essence of vanilla, a little warm water. Cream butter and sugar, add egg, flour, enough warm water to mix into stiff dough. Roll out and spread with icing made with white of egg and ¼lb. icing sugar, flavour with vanilla, scatter chopped walnuts on top and cut into fingers. Bake in a moderate oven. *Raspberry Sandwich Biscuit*: 4 cups flour, 1½ cups sugar, ½lb. butter, 3 eggs, 2 teaspoons c. tartar, 1 carb. soda. Roll out

as thin as possible, cut and bake in a quick oven. Spread jam between while hot. *Shortbread Creams*: ¼lb. butter, 2ozs. sugar, ½lb. flour, 1 teaspoon c. tartar, ½ carb. soda, yolk of 1 egg, little warm water. Cream butter and sugar, add egg, then dry ingredients; roll and cut into shapes, and bake. When done join two together with icing. *Melting Moments*: 6ozs. butter, 7 tablespoons plain flour, 2 tablespoons each cornflour and icing sugar. Beat butter to a cream, then add dry ingredients. Make into little balls with the hands and press on top with a fork. Bake in a slow oven. *Glenroy Biscuits*: ½lb. butter, ¼lb. sugar, ¾lb. S.R. flour, 2 eggs. *Brown Biscuits*: 2 cups rolled oats, 1 cup sugar, 6ozs. butter, 1 cup cocoanut, 1 teaspoon vanilla, 1 teaspoon carb. soda in 4 tablespoons boiling water, 1 tablespoon each treacle and golden syrup. *Cheese Biscuits*: 3ozs. flour, ¼ teaspoon baking powder, 2ozs. grated cheese, 1oz. butter, pinch salt, yolk 1 egg, squeeze lemon juice, a little cayenne, and a little cold water to mix. *Sao Biscuits*: 2 cups flour, 1 tablespoon cornflour, pinch salt, ¼ teaspoon baking powder, sift together and rub in 2 tablespoons butter. Mix to a stiff dough with a little milk. Roll out very thinly, cut with round cutter and prick with a fork. *Shrewsberry Biscuits*: ½ cup flour, ¼lb. sugar, ¼lb. butter, 1 egg, flavouring or 1 teaspoon lemon juice. Cream butter and sugar, add egg. Roll into balls and dip in sugar. Bake on greased slide, press flat with prongs of fork, pressed both ways. Bake 15 minutes. *Spiced Honey Nuts*: 2ozs. each butter and sugar, 1 egg, ½ cup honey, 6ozs. S.R. flour, pinch salt, 2 teaspoons cinnamon, 1 cup nuts. Drop in teaspoons on greased slide, leaving room to spread. *Chocolate Biscuits*: 4ozs. flour (S.R.), 2ozs. each sugar and butter, 1 egg, ¼ teaspoon vanilla, ½ teaspoon mixed spice, 1 dessertspoon cocoa, a few chopped almonds (pinch salt if desired). Cream butter and sugar, add egg, and beat well. Add vanilla, spice, and cocoa, then sifted flour. Put through forcer on to greased slide, sprinkle with chopped almonds. Bake in moderate oven 10 minutes. *Ginger Biscuits*: 2 cups flour, 1 cup sugar, 6 level tablespoons dripping, 2 tablespoons treacle, 3 tablespoons ginger, 2 eggs, 1 teaspoon c. tartar, ½ carb. soda. Beat sugar and dripping, add eggs, treacle, and ginger, add flour and rising. Drop on greased slide. If rolled in the hands they make a better shape. *Afternoon Tea Biscuits*: 3 tablespoons each flour, cornflour, sugar, and butter, 1 teaspoon c. tartar, ½ carb. soda, mix with 1 egg. Roll out thinly, cut into shapes. Bake 10 minutes. *Avon Biscuits*: ¼lb. butter, ¼lb. sugar, 3 cups sugar, 2 teaspoons c. tartar, 1 teaspoon soda, sifted in flour, 1 egg. Rub butter in flour and sugar, mix with yolk of egg beaten in ½ cup water. Roll out and ice with icing made with white of egg and icing. Cut into fingers. Bake 10 minutes. (Secretary, Mrs. E. Kidman.)

July 4th.—Attendance, 42.

A butter competition was held. Forty-one competitors entered for the trophy presented by Mr. A. Robertson of Struan House. The Government Instructor (Mr. W. H. Downes) judged and commenting on the standard of exhibits said there was marked improvement on the 1933 competition. Mr. Downes discussed exhibits with the owners and gave practical advice as to improvement. The successful competitors were:—Miss McCorquindale, first; Mrs. R. McDonald, second; Miss F. McDonnell and Mrs. Clifford, tied third. (Secretary, Mrs. E. Kidman.)

PICKLING GHERKINS SO THAT THEY RETAIN THEIR GREEN COLOUR.

The first requisite to success in pickle-making is good vinegar—strong and pungent. Gherkins need only to be washed and drained thoroughly to be ready for pickling. Do not use a copper vessel in any part of the process of pickle-making, but use instead a porcelain-lined preserving vessel. Vinegar boiled in copper forms acetate of copper, which is poison. To retain the green colour of gherkins, add parsley to the vinegar some days before pickling, and let it steep until ready for use, when the vinegar ought to have a decided green colour, which colour will of necessity be imparted to the gherkins. The process is then as follows:—Take, say, two hundred gherkins. Cover with cold water, to which add a pint of salt; let stand over night. In the morning drain off the water, then measure and take as much vinegar (coloured by parsley) as you have water (i.e., drained from gherkins), 1oz. of allspice and a piece of alum the size of a walnut. Boil the vinegar and spices, etc., and pour, boiling hot, over the gherkins. Cover with green cabbage leaves. A few green peppers in the vinegar give an added flavour and are a great improvement.—*New South Wales Agricultural Gazette.*

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

River Murray Swamp Areas, at Murray Bridge (Jervois Branch), Thursday, February 21st (F. P. Baily, Woods Point, Secretary).

Yorke Peninsula, at Kadina (Boor's Plains Branch), March 6th, S. G. Chynoweth, (Secretary).

Mid-North, at Redhill, Thursday, March 14th (S. A. Pengilly, Secretary).

South-East (Upper), at Mundalla, Wednesday, March 20th (A. Ross, Secretary).

South-East (Lower), at Mount Gambier, Wednesday, April 10th (G. T. Gurry), Secretary).

River Murray, at Moorook, Thursday, June 20th (S. Perkins, Secretary).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Standard Cornsacks.

Following the Congress resolution relating to cornsacks, the Collector of Customs states that the standard for new cornsacks as prescribed by proclamation is as follows:—Size, 41in. by 23in.; weight when baled, 2¼lb.; substance, 8 porter, 9 shot. The importation of secondhand cornsacks is authorised, provided they comply with the following conditions:—(*a*) That as regards size and weight the sacks do not vary more than 5 per cent. from the standard prescribed for new cornsacks; (*b*) that the sacks are approximately of standard porter and shot; (*c*) that the sacks are clean and free from patches and holes. The importation in the Commonwealth of cornsacks other than those complying with the foregoing standards is prohibited, and any importation made of cornsacks not complying with the proclaimed standard would be liable to seizure and confiscation under the Customs Act.

Arsenate of Lead—Analyses of Samples.

It is usual for the Department of Agriculture to collect each year from local manufacturers the various brands of arsenate of lead powders which they have for sale and to submit the samples to analyses for the information of fruitgrowers and others. This year the samples were collected in October, and the Analyst's report on them reads as folows:—

"The samples (six) of arsenate of lead powders, received on November 12th, 1934, No. 517, have been analysed with the following results:—

No.	Brand.	Moisture.	Total Lead (PbO)	Total Arsenic (As_2O_5)	Water Soluble Arsenic. (As_2O_5)	Suspension Test. Five Mins.	Suspension Test. Thirty Mins.
		%	%	%	%	%	%
1.	"Vallo"	0.52	64.0	30.9	0.11	32.8	10.7
2.	Hemingway's	0.53	64.4	31.4	0.14	83.0	60.3
3.	"Aero"	0.68	64.5	31.3	0.17	64.0	45.4
4.	"Lion"	0.27	64.0	32.0	0.11	25.6	9.0

6.	"Palmprest"	0 25	64.6	32.0	0.17	35.2	9.1

Dehorning Calves.

Replying to the Secretary of the Mangalo Branch of the Agricultural Branch, who asked (1) the correct age when to dehorn cattle, and (2) how to dehorn calves six months of age, Mr. C. McKenna, B.V.Sc., M.R.C.V.S., of the Stock

and Brands Department, says the best age to dehorn cattle is when calves are two-three days old. At this age the horns are present as "buttons" loose from the skull Clip hair away around these buttons, moisten them with water and rub until soft. Then a stick of caustic potash should be carefully touched with water and rubbed into skin over embryo horn. Do not have sufficient water to allow it to run down the side of the face—this will burn off hair and cause sores. When the scab over the horn falls off, apply the caustic stick a second time. The best way to do the calves six months old is to throw them and cut off the horns level with the skull with a sharp broad chisel. Stop the bleeding by applying a hot iron and dress with the following dressing:—Creosote, 1 part; oil of turpentine, 6 parts; raw linseed oil, 20 parts.

Greasy Heel in Horses.

Mr. A. H. Robin, B.V.S. (Stock and Brands Department) advises the Secretary of the Miltalie Branch of the Agricultural Bureau that if the case is one of simple greasy heel, where the lesions are superficial and situated below the fetlock, it will readily respond to the following simple treatment:—Clip hair from affected part and wash the part thoroughly with soft soap and water in which is dissolved some washing soda (at the rate of 1 teaspoon to the pint) to remove scabs, &c., after which the part should be carefully dried with a clean soft cloth. Then dress affected part twice daily with the following lotion:—Liquor plumbi subacetatis, 1oz.; methylated spirits, 8ozs.; water, 1 quart. When weeping on the part is checked, complete treatment by daily applications of zinc ointment. The horse should be kept at rest on dry, clean standing. If the condition is the more serious one known as "grease" and extends over the fetlock and up the back of the leg, it will prove much more difficult to deal with. If taken in the very early stages, the application of the lotion mentioned above may check the trouble. If the case, however, is more advanced, the following treatment should be tried:—Rub in to the affected area some liquor ferri perchlor. fort., applying this on a piece of tow or cotton wool wrapped round one end of a piece of stick. This dressing should be applied every three or four days to begin with and later once a week. If after a time applications of this seem to lose effect, rub in daily for a week the following powder instead:—Boracic acid, powdered lime, common salt (equal parts of each). Then resume the treatment with the iron solution. After the preliminary washing at the commencement of treatment, do not wash the parts again—this is very important. Remove any discharge, &c., subsequently by rubbing with clean cotton wool.

Polished Clover Seed.

Replying to the Secretary of the MacGillivray Branch of the Agricultural Bureau, who asked: "What effect does the polishing of clover seed have on its germination, Mr. R. C. Scott (Superintendent of Experimental Work) says the polishing of clover seed would not have any effect so far as a reduction in the germination percentage is concerned. In the case of some tough-skinned clovers, such as Strawberry Clover, it is quite a common practice to subject the seed to a rubbing process with sand or emery paper to improve germination, and such action would probably be of advantage to the proportion of hard seeds which Subterranean Clover usually contains. However, the ordinary polishing to improve the appearance of the grain for commercial purposes would have no influence on its germination.

Breeding, Feeding, and Diseases of Sheep.

The Library of the Department of Agriculture acknowledges the receipt of the October, 1934, number of "The Veterinary Journal—an issue devoted solely to the Breeding, Feeding, and Diseases of Sheep." Copies of the journal can be obtained from Messrs. Bailliere, Tindall & Cox, Henrietta Street, Covent Garden, London, W.C.2, at the price of 2s. 2d., post free.

GENERALITIES CONCERNING FARM POULTRY.

[Paper read by C. F. ANDERSON (Government Poultry Expert) at the 45th Congress of the Agricultural Bureau.]

Because of the fact that during recent years more attention is being devoted to the poultry industry, with a natural desire for more information as to the methods to be adopted, the following points concerning various branches of the industry should be of interest.

Poultry keeping has been practised for many years. In Gent's *Systema Agriculturae* published in 1675, the keeping of fowls for profit is advocated and advice given as to management, but it contains no description of the different breeds.

POULTRY ON SMALL HOLDINGS.

From a State point of view, it is generally accepted that there are possibilities for further extension of smaller holdings in various parts of the State, and more especially in the Southern and Hills Districts, where climatic conditions are very suited to the production and marketing of a perishable product such as eggs. There are, however, other parts of the State—especially where marketing facilities are available—that offer opportunities for the further development of the poultry industry.

In reading this paper the fact should be kept in mind that it is written from the point of view of poultry being kept as a side line to general farming, and not as a sole means of livelihood.

It appears that to a large extent, the greater extension of the industry from a commercial egg producing aspect, will come from the farming areas.

This is an economic factor which must be given serious consideration. In the last few years a marked expansion has taken place in the rearing and keeping of large numbers of poultry in the suburban areas, and while, no doubt, this can be attributed to the depression, people with a block or two of land in the suburban areas have undertaken the keeping of poultry in order to obtain some return. We are, however, concerned to-day with reducing costs of production to the minimum, as South Australia in particular, with its large surplus production is fighting on a competitive method for the existence of the industry. The average farmer has distinct advantages over the suburban producer in production costs. The land necessary for the keeping of poultry is available on the average farm, the cost of feeding is also reduced to the minimum, as practically all the foodstuffs necessary for the production of eggs are grown on the farm. This is a distinct advantage as the suburban man has to buy ali necessary foodstuffs, and in districts where water supplies are available, and suitable for the growing of green-fodders, there is no reason why eggs of the highest quality cannot be produced on the average farm.

OCCUPATION FOR YOUTHS.

There is another important aspect that should be considered, and that is the possibility of the employment of the younger generations on the farm. This factor is puzzling the minds of the majority of parents, and I believe that where boys and girls show any inclination towards the

care of poultry, they should be given the opportunity of extending their knowledge in order that they can, with a reasonable amount of safety, extend the numbers of their poultry.

The Education Department is doing good work in this direction under the Home Project Clubs and already there are many boys in various parts of the State who have flocks of several hundreds of birds, and who are obtaining satisfactory returns from them.

In the Egg Laying Competition conducted at Parafield Poultry Station there is a separate section for Home Project Workers, in which twenty-two boys from various parts of the State have birds competing, and it is very pleasing to see that some of the birds are recording excellent scores.

REQUIREMENTS OF THE MARKET.

There is one all important factor that should be very carefully studied before any definite effort is made in the poultry industry, and that is the requirements of the market. Producing eggs and marketing them continually in a haphazard manner is only courting disaster. The day when an egg, irrespective of the quality, was worth as much as the better quality egg is gone, and unless producers are prepared to give attention to the marketing aspect, they would be well advised not to undertake the keeping of poultry. To argue that it requires special skill, etc., to produce eggs of the quality desired cannot be substantiated. It is barely 12 months ago when the settlers on the Land Settlement Scheme, under the control of the Employment Promotion Council received their first supply of poultry, and very few of these settlers had any previous experience with the keeping of poultry. During the last three months practically 100 per cent. of the eggs marketed by these settlers have passed the grading for export. There have been isolated instances where a few eggs in a case have been rejected, but the percentage rejected compared with the quantities pooled has been infinitesimal.

The overseas exports are under the control of the Department of Commerce, and all eggs submitted for examination are subjected to very close inspection. The regulations state:—

1. "Fresh" in relation to eggs in shell, means that the eggs are fit for human consumption, and are considered by an officer, after examination by the "candling" process, to be not more than seven days old.
2. Any egg, which has a broken or damaged shell, or which is in an unsound, unclean, or other abnormal condition, shall not be packed.

The two principal causes for rejection are—eggs being held too long on the farm before marketing, and so deteriorating in quality; and eggs rejected on account of dirty shells. Both these conditions are such that can be considerably minimised in a large number of cases. There is another aspect that does not receive the attention that it should, and that is our home market or local consumers.

THE LOCAL MARKET.

None of us can close our eyes to the great importance of maintaining quality for export up to the very highest standard, as any slackening in this direction would result in the poultry industry losing the principal

market for our surplus production, but this is no reason why dirty shelled eggs, eggs of poor quality, etc., should be foisted on our local consumers. There are no statistics available concerning the average consumption of eggs in this State, but from what one frequently sees exposed for sale as eggs, the probabilities are that the consumption is not very high In fact during certain months of the year frequent requests are received by the Department enquiring where eggs of good quality can be obtained. If the annual consumption of eggs in the State were increased only by a dozen per head, the increase would be equal to some 580,000doz., and this should be easily attained if the public were assured of buying eggs which were not only attractive in the condition of the shell, but also of good quality, without the combination of egg and chicken in the shell, as is frequently experienced.

THE ADVANTAGE OF THE INFERTILE EGG.

In a climate like South Australia, the advantage of the infertile egg as a marketable product cannot be over-stressed. It should be kept in mind by all producers that in addition to overseas exports, South Australia sells annually interstate approximately 1,000,000doz. as eggs in the shell, and as interstate eggs travel under ordinary conditions without refrigeration, the value of the infertile egg is evident. Germination of the embryo of a fertile egg commences at a temperature of approximately 70deg., and when it is realised that the bulk of country eggs are produced when the temperatures are anything from 80deg. to 100deg., the enormous loss in quality of the eggs can readily be understood.

In addition there are considerations such as the extra amount of food consumed by the surplus cockerels, and the amount of housing accommodation they occupy, which could be more profitably used by the pullets and hens.

In considering the question of keeping poultry on the farm, I will now attempt to indicate the methods along which we should proceed. I believe that the principal factor to be considered is the extent to which a side line can be handled on the farm without interfering with the more important work of the holding. Generally speaking, however, the women folk give most attention to the poultry on the farm, and this fact therefore counteracts the belief that the keeping of poultry on the farm is more or less a drag on the farmer himself.

The question, however, that must be kept in view is that of marketing, and in order to obtain the best returns it is essential that the eggs be marketed twice a week during the summer months, and in order to make this economically possible sufficient birds should be kept so that a case of eggs can be marketed at one time from three hundred to four hundred birds.

REPLACEMENT OF FLOCKS.

Another aspect which should be understood is that in order to ensure a regular return from the flock, replacements of a percentage of the flock are necessary each year. It is suggested that if a flock of three hundred birds are kept, thirty per cent. of them should be replaced each year; if this plan is followed, it will be possible to have a fairly regular supply of eggs each month of the year. It is very doubtful whether any bird after three laying seasons is worth keeping for the production of eggs

only. There are, however, exceptions to this practice, where special birds can be kept for breeding purposes for a season or two longer. On the majority of farms one frequently hears that during the months of April and May there is a shortage of eggs, even for the household. This is due to the fact that the old stock are moulting, and that no young stock have been reared to come into production during the winter months, and until producers in general realise that pullets are the only class of stock that will lay any number of eggs during the winter months, a shortage of eggs during that period will continue.

IMPROVEMENT OF STANDARD OF FLOCKS.

The general standard of farm poultry in this State to-day is not very high. All ages of birds, both males and females, can be seen running together, and it is rather difficult to suggest just where to commence in the rebuilding of a better class of stock. The better course in the majority of districts would be to commence with fresh lines of stock, keep them separate, and gradually dispose of the present stock. With the little attention that has been given to the breeding of farm poultry, it is difficult to suggest any other course; flocks have been running together for many years, and have been continually bred from, without much attention being given to the selection of the breeding stock—a method which is not likely to improve the standard. There are probably many thousands of poultry running on our farms to-day that are only laying a few eggs a year, and this is likely to continue unless the present methods are altered. The principles in poultry keeping that should be understood are—the first laying season is the most profitable one, in the second season the birds that have been proved the best layers in the first season should be used as breeders, and a portion of only the very best of them retained for the third season. No birds over three years of age should therefore be retained. The question of selection of stock is not a difficult one. There are numerous breeders of high class poultry in the State, and a start could be made with the purchase of a breeding pen or two, the purchase of fertile eggs for incubation, or the purchase of day old chicks, or the purchase of pullets at from eight to ten weeks of age, when the risk of rearing same is practically eliminated. Where fertile eggs or day old chicks are purchased there is always the risk of losses in rearing which must be considered, and unless reasonable facilities are available, these losses will frequently be heavy.

The question of breed is one that rests almost entirely with the farmer himself, but in any case the selection of breeds is not very wide. Up to the present time the production of eggs has been specialised in this State, and it appears the right course to continue. This being the case, the choice of birds is limited practically to the White Leghorns, Black Minorcas, Black Orpingtons, and Rhode Island Reds. The capabilities of the Leghorns and the Minorcas are too well-known to require further explanation. Where the dual purpose bird is required, the Black Orpington or Rhode Island Red should supply the needs, with a preference for the latter because when the overseas export of table poultry is re-established, the Rhode Island Red will be the more suitable bird. In any case it is very doubtful whether the export of the Black Orpington as a table bird is advisable, owing to the prejudice on the English market against a bird with black legs.

Whatever breed is decided on, efforts should be made to commence with only the best stock, the aim of which should be the production of the maximum number of 2oz. eggs and over. This is of the greatest concern, as no stock that does not produce the full sized egg should be used for breeding. This necessitates keeping the size of the bird up to standard, because, generally speaking, as the size of the breed deteriorates so does the size of the egg as well as the general constitution of the stock, thus making hatching and rearing more difficult.

TABLE POULTRY.

To those contemplating specialising in the production of table poultry; and there is undoubtedly room for more attention in this direction from the local market point of view; a few points may be of interest. The general demand to-day is for the medium-sized bird; one that dresses at from 3½lbs. to 4lbs. The aim should be to get this weight as quickly as possible, and it should be attainable with any of the principal heavy breeds at from 5 to 5½ months of age. It should be recognised at first that birds will not fatten readily if allowed unlimited free range, as they lose a good deal of condition by the constant foraging and running about on range. The ideal method is to give them range as the frame of the bird develops, until they are from 3½ to 4 months of age. They should then be confined to small coops or batteries each to accommodate from six to eight birds. These batteries can be cheaply constructed from wire-netting and light timber, a design of which can be seen at Parafield Poultry Station. Mash is fed two or three times a day. It is only necessary to hold the birds for three and four weeks at the longest in the battery, and it will be found that the birds will put on from 1lb. to 1½lbs. during this period.

HATCHING MONTHS.

For either egg production or table purposes the hatching periods should be limited to certain months. This practice is difficult to adopt where reliance on the broody hen as a method of hatching is necessary, but with modern methods of hatching by the latest all-electric mammoth incubators, the cost of hatching is comparatively cheap. There are several of these hatcheries in the State and the benefits of seasonable hatchings cannot be too strongly stressed. Similar to the majority of other lines of production the early stock are to be preferred to the late stock, especially in the hotter districts. The advantages of rearing the young stock on early grasses are not fully recognised, whereas with the late stock—October and November hatchings—the succulence of the natural grasses is practically lost and the stock, instead of having free access to abundance of young and tender grasses, are limited to dried-off fields, with the result that they are slower in maturing, and, owing principally to the absence of green feed, do not come into production until June or July. A good practice is to start hatching operations early in July, according to the district and breeds kept, and finish hatching by the end of September. Early September hatching, however, is probably the ideal for most parts of the State. If it is desired to have two hatching seasons in the year, I would advocate also hatching during the latter part of January and through February.

HOUSING.

The method of housing is also worthy of consideration. As mentioned previously in this paper, one of the principal causes for rejects from export is the dirty-shelled egg, and this factor is one closely allied with housing and nesting. If the habits of poultry are closely studied, it

will be found that 70 to 80 per cent. of the eggs produced are laid by noon to 1 o'clock. therefore if the houses are built sufficiently large and sufficient nests provided the number of dirty-shelled eggs will be greatly reduced. Approximately four square feet of floor space should be allowed for each bird. The houses should face north or a little east of north, and it will be found that a hundred birds in one flock will probably give the best results.

One nest to every six birds or sixteen nests to the hundred birds will be sufficient. Two to three inches of clean sand or shell grit should be kept in the nests. This is preferred to straw or cocky chaff, as sand or shell grit do not stain the shell of the egg to the same extent as do straw and cocky chaff. If the nests are kept from 15in. to 18in. above the floor they will help to keep the eggs clean. On the average farm where straw is available about 6ins. of straw should be kept on the floor of the house, except under the perches, where sand should be provided. When choosing a site for the poultry-house select one that is dry, as it is important that the floors should be kept dry. It will be found that if the floor of the house is first levelled and rammed hard, and 1in. wire-netting pegged down on the ground, with the litter placed on the wire netting, it will help to keep the litter dry and also prevent the birds from working big holes in the floor.

The perches should be arranged so that they are not suspended from the roof or fixed to any part of the walls or ends, especially where there is any danger of poultry tick, and a clear space of at least 1ft. between the perches and walls of the houses should be allowed. The perches should be of 3in. x 2in. timber rounded on one 2in. surface; 8in. of perching space should be allowed per bird, and the perches should be from 12in. to 14in. apart, and from 15in. to 18in. high, keeping them all on the one level.

FEEDING.

This is an all-important question, as no matter what the breeding of the stock may be, unless they are properly fed the results will not be satisfactory. Continued feeding experiments have been conducted at Parafield Poultry Station to obtain data as to the most suitable methods that could be adopted, keeping in mind the particular foodstuffs that were available on the average farm. For a number of years it has been considered that for the profitable production of eggs the feeding of both bran and pollard was essential, and while not in the least depreciating the value of bran and pollard as a poultry food, it was not an economic practice for the average farmer, especially in districts where mill offal was difficult to obtain, to feed bran and pollard if other suitable foodstuffs were available on the farm. There are two aspects, however, to be considered and that is feeding solely for egg production and feeding for breeding, and I would definitely state that the conclusions to be given are only from an egg-producing point of view. Experiments in regard to the effects of the various methods of feeding on fertility and hatchability are still in progress. It is recognised that the principal foodstuffs available on the farms are wheat and barley, and a ration which has given very favourable results is—

Morning—Wet mash, composed of 1 part crushed barley, 2 parts wholemeal by weight, 1lb. meat meal per 100 birds, 50 per cent. chopped greenfeed.

Mid-day—Wheat.

Night—Wheat.

Where it has not been practicable to feed a wet mash, the same mixture of meals and meat meal, mixed dry and fed in hoppers, has also given satisfactory results. The basis of quantity per bird a day is crushed barley ½oz., wholemeal 1oz., wheat 2ozs.

A very interesting comparison of the difference in production of the above methods to those adopted by the ordinary farmer, that is, of feeding wheat night and morning, is shown by the production of the same number of birds in each pen, that is 50 birds, over a period of sixteen months:—

	Number eggs laid.
Wet mash pen	8,864
Dry mash pen	8,237
Wheat pen	4,217

The Wet Mash pen laid more than double the number of eggs of the pen fed on all wheat as a grain.

THE BAROMETER OF THE POULTRY INDUSTRY.

The following figures supplied by the Government Statist reveal the growth of the poultry livestock of the State during the last four years:—

Year 1929-30	1,665,818 head
1930-31	1,759,054 "
1931-32	2,033,512 "
1932-33	2,109,592 "

The overseas exports of eggs in shell from South Australia for corresponding years are also very illuminating:—

Year 1930	772,680 dozens
1931	1,961,400 "
1932	3,702,450 "
1933	4.181,640 "

It is believed that there is still room for increased production of poultry and eggs in the wheat-growing areas of this State, and if the general advice given in this paper is closely followed, the poultry industry will still increase in production and hold the position of one of the most important primary industries of this State.

INDIGESTION IN FOALS.

"Narridy" reports foals two months old eating dirt and manure. This question was referred to Mr. A. H. Robin, B.V.Sc., of the Stock and Brands Department, who says the indications are those of indigestion. The commonest cause of this trouble in suckling foals is some trouble with the mare that renders her milk indigestible; overworking or overheating of the mare will also cause her milk to have the effect of upsetting the foal. It would be advisable in such cases to give the foal a drench of ¼ pint of olive or raw linseed oil, and at the same time give the mare a drench of raw linseed oil, 1½ pints; oil of turpentine, 4 tablespoons; following this with a heaped tablespoon of baking soda night and morning in damped feed for a few days.

QUALITY OF DAIRY PRODUCE AND ITS EFFECT ON MARKETING CONDITIONS.

[Paper read by H. B. Barlow, H.D.A. (Chief Dairy Instructor), at the Forty-fifth Congress of the Agricultural Bureau.]

In discussing this question I am thinking particularly of the chief product of the dairying industry, namely, butter, but at the same time the position of cheese, condensed milk, and even liquid milk must not be overlooked.

Anyone who takes a long-sighted view of the matter must of necessity admit that high-quality products always control a much readier market than shoddy or inferior goods, and this fact should always be kept well in mind when considering the marketing of our dairy produce to the best advantage either locally or on an overseas market.

The butter production of South Australia for the years 1931-1934 was as follows:—

	1931-32.	1932-33.	1933-34.
Factory butter	13,828,764lbs.	17,161,664lbs.	15,189,656lbs.
Dairy butter	3,834,265lbs.	4,148,342lbs.	4,426,388lbs.
Exports	7,400,628lbs.	9,500,027lbs.	8,308,420lbs.

Percentage of Grades.

	Boxes.	Boxes.	Boxes.
Choice grade	37,379 = 27.25%	50,770 = 29.16%	43,872 = 27.33%
First grade	68,777 = 50.69%	101,331 = 58.20%	93,627 = 58.34%
Second grade	26,036 = 19.19%	16,790 = 9.63%	14,097 = 8.78%
Pastry grade	3,600 = 2.60%	5,214 = 2.99%	8,884 = 5.53%

Local consumption is estimated at about 20lbs of butter per head which, with a population of 580,000, represents a consumption of about 11,600,000lbs. per year.

An estimation of the quality of the butter consumed locally, without taking dairy butter into consideration, would be about 30 per cent. Choice Quality, 50 per cent. good First Grade, and 20 per cent. Second Grade.

The estimated per capita consumption of butter in Australia is about 27lbs. per head, and the per capita consumption in New South Wales is about 31-32lbs. per head, and represents about 41 per cent. of the total consumption in Australia.

In considering these figures it is probably advisable to point out that good First Grade and Choice butters only are suitable for table use. On this basis it is apparent that not more than 75 per cent. of our factory butter is fit for table use, barely 30 per cent. of this butter is of Choice quality, and it is doubtful if 50 per cent. of farm butter could be classed as even First Grade, and practically no farm butter could be designated Choice Grade.

From these figures it would appear than in South Australia we are, generally speaking, supplying our local consumers, who after all are our best and most valuable customers, with a mediocre article. It might be suggested, why stress this fact as long as the consumers will buy our product? It is definitely a fact that it is cheaper and easier to make a mediocre article than a high quality product, but does the small saving obtained by this short-sighted policy in any way compensate us for the financial loss which occurs to the producer and the State generally?

As a matter of comparison let us consider the comparative position in New South Wales. It is estimated that in New South Wales approximately 85 per cent. of the butter manufactured is of Choice Grade, or of the very highest quality, and the per capita consumption is 31-32lbs. per head of population. During the last 20 years the quality of butter manufactured in New South Wales has been gradually improving in quality, and during this period—at least up to the start of the so-called "depression"—the per capita consumption gradually increased, and moreover this increase was brought about, not by costly schemes of advertising, etc., but simply by educating the general public's taste for a high-grade butter, and on account of the improved palatability increasing the consumption enormously. Figures from other States could be quoted which definitely prove that the better the quality of butter supplied the greater does the per capita consumption become.

From the point of view of the Commonwealth it is doubtful whether increased per capita consumption would be a direct advantage since an increase of 5lbs. per head in consumption would tend to lower our exportable surplus by about 30,000,000lbs. per year, but from the point of view of the producers the added income would be a very valuable consideration. Consider the position as it is to-day and has been for some years throughout Australia. The price paid by consumers for butter in Australia is in the vicinity of 140s. per cwt., and the value of the same butter in London is only about 70s. per cwt.

Taking these figures into consideration it is very easy to conceive what a great advantage it would be to all producers in South Australia if we could raise our per capita consumption to even slightly below that of New South Wales, which would mean an approximate increase of about 10lbs. per capita. With a population of 580,000 this would give us a total consumption of 17,400,000lbs. out of a total production (including farm butter) of 19,616,044lbs., or in other words our producers would be credited with the high Australian price for all the table butter made in the State instead of only about 60 per cent. as at present.

There is no doubt in my mind that, if not wholly at least in part, it is possible for us to realise this improvement, but it cannot be done without a really conscientious endeavour being made by all concerned. I do not for a moment wish to infer that the mediocre quality of our butter as a whole is due solely to laxity on the part of the producer, but we cannot afford to forget the fact that good quality cream is the basis of high quality butter.

It is only necessary to go on the cream-receiving platforms of factories to realise what mixed ideas producers seem to have of a suitable cream for butter making. You will see cream testing as low as 30 per cent. and up as high as 60 per cent. of butterfat—varying in age, acidity, smells, flavours, temperatures, and physical condition! Cream too thin containing coagulated curd, creams so thick that they are with difficulty removed from the cans, and unmixed creams showing a different layer for each separation. Some of the creams are contaminated from unwashed separators or partly washed milking machines and utensils, and suppliers expect factories to produce choice butter from them all.

Given good clean cream, cared for and delivered by the farmers as it should be, it would be difficult to make butter in the average modern factory below choicest quality by standardised methods, but it is very difficult to make even passably good butter from inferior cream in the very best factories and with highly trained operatives.

There is no doubt that the initial cause of so much mediocre butter being made in South Australia is the fact that a large percentage of the cream delivered to the factories is of inferior quality, and to a great extent the factories, by what is called competition, foster this mediocre supply Because of this competition factory managers have been induced to mix inferior creams with choicest creams, thereby lowering the average quality and spoiling the market for their goods. To try and avoid grading cream and paying for quality factories have spent thousands of pounds on costly equipment, and have been experimenting with various processes of neutralising, pasteurising, and deoderising in a way that was never intended in order to try to do the impossible, that is, make good butter from bad cream. Surely the producer of South Australia is not going to admit that unless his cream is renovated it is not suitable for making good butter?

I have tried to indicate that in my opinion an improvement in the quality of our table butters can be expected practically for certain to have a direct effect on our per capita consumption with a corresponding increase in financial returns. Besides being true with regard to our local market it is only reasonable to expect that an improvement in the general quality of our Australian butter would show a definite improvement in price levels. Although it is usually stated that there are only a few shillings difference between the export parity of our good and inferior butters, the value of a higher quality is illustrated by the fact that certain Australian brands of butter which consistently grade high points for flavour obtain a price premium over other Australian Choice brands in London, showing that consistent high quality does have an effect on the financial returns.

I have brought this matter up for discussion because in my opinion the marketing legislation recently adopted in Australia, although it will definitely tend to stabilise the price of good butter, might, in my opinion, have the ultimate effect of tending to increase the margin of values, good quality, and lower grade of produce. If this is so, South Australia, with a relatively high percentage of inferior butter may ultimately be at a disadvantage as compared with the Eastern States unless we make every endeavour possible to decrease our percentage of inferior produce.

THE PRODUCTION OF FAT LAMBS.

[Paper submitted by MR. T. R. SECKER (Yalluna Station, Tumby Bay), at the Forty-fifth Congress of the Agricultural Bureau.]

It is generally recognised nowadays that wheatfarmers must keep sheep to hope to get full returns from their farms, that the best results are secured by farmers from a breeding flock rather than by dabbling in dealing with sheep, and that where distance to market is not too great and transport facilities are fair, the production of fat lambs gives the farmer a chance of making a greater profit than does breeding for wool alone. This has proved so for a long time where farmers are not more than 150 miles or so from the Adelaide market, and of recent times similar results are being realised for Eyre's Peninsula since the Port Lincoln Freezing Works have been opened each season for the slaughtering and exporting of fat lambs.

The climatic conditions, and the requirements of the overseas market are the deciding factors in deciding which type of fat lamb will prove most profitable, and fortunately sufficient experience has been had in the State to know that the relatively short, dumpy, broad-backed lamb, with well-filled hindquarters, the dressed carcass of which weighs from 32lbs. to 36lbs., as required by the British market, can be produced with certainty in many districts of South Australia, and certainly so in southern Eyre's Peninsula.

The type of ewe to produce the desired lamb, and at the same time give a reasonable return for her fleece will vary according to circumstances, but if export lambs are the aim the choice of ram is strictly limited.

THE MOTHER OF THE FAT LAMB.

In some districts farmers have no choice but to use Merino ewes as the mothers of the fat lambs—at all events when they commence this form of sheep management—but in many cases this will be altered as time goes on. On Eyre's Peninsula, Merino ewes are now on many farms, or at all events they can be readily procured, whereas some difficulty would be experienced in securing crossbred ewes of any type suitable for producing fat lambs.

MERINO EWES.

If Merino ewes are to be used, select big-framed, robust ewes from 6-tooth to 5 years old, which as a rule will give bigger lambs, a better percentage of lambs, and will look after the lambs better than will 4-tooth maiden ewes. Such ewes will also give a good wool return.

These Merino ewes should be mated to one of the Downs breeds of rams, say, about the middle of December for southern Eyre's Peninsula. At least two rams to every 100 ewes are needed to ensure an even drop and they should be left in for a period of eight weeks. The lambs should start to come along about the middle of May, which is early enough as there is then a better chance of having some green picking than if lambed earlier. Some farmers prefer to have their lambing all over before cold weather sets in; if so, then the ewes will have to be mated earlier. There is this danger in having the lambs too early, they are likely to receive a severe check which takes a lot of making up again. Lambs which have been severely checked never make the lambs they would if they had not received this setback early in their lives.

The Merino ewe has the big advantage that she will mate any time, which is not the case with most crossbred ewes.

CROSSBRED EWES.

Crossbred ewes are far bigger framed than the Merinos, have a better milk supply, and give a bigger and quicker growing lamb. But some of the crosses will not mate perhaps as early as one may desire and mate better in the latter end of January and during February.

The Corriedale-Merino crossbred ewe will mate earlier than most of the other crossbreds, and seems to be an ideal ewe for fat lamb raising in our agricultural areas. She is a splendid mother, has great constitution, cuts a valuable fleece of wool, and when finished for breeding will readily fatten and command good money. Another point that cannot be lost sight of, with perhaps uncertain markets, is that the Corriedale-Merino crossbred ewe has a big advantage over other crossbred ewes for if, at any time, one wishes to go back to wool growing alone one has a ewe that will give the quickest and best results.

THE RAM TO SIRE THE FAT LAMB.

The Corriedale ram crossed on the Merino ewe gives a very nice lamb, but has a bit too much leg, and therefore not a really good export lamb, still, by keeping the ewe lambs of this cross as future breeders to be mated with a Southdown sire, seems to give pretty near the ideal lamb.

The favourite is the Southdown as a sire for fat lambs for export, from either Merino or crossbred ewes. No individual ram, in a sense, is too good for this job. The dearer class of ram is far the better to use, and it is noticeable that he is generally very short in the scrag, broader in brisket, wide across the shoulders, has well-sprung ribs—in fact the same width from shoulder to tail—and better filled-in in the breech and carrying the leg fairly full to the hock, giving a ham-like leg, and is well worth the extra money asked as against the cheaper-priced ram.

The Ryeland ram was tried as a sire for the first time this season at Yeelanna, crossed with Corriedale-Merino crossbred ewes. These lambs are very promising, and have grown quickly in spite of the unfavourable start to the season. These lambs are very much like the Southdown in shape, but larger, and carry more bone, and it appears that they would have to be marketed as soon as ready or they would quickly get on the heavy side. The use of this ram for crossing is likely to become more general and should prove profitable.

FEEDING THE FLOCK.

One of the main things helping towards success is feeding the flock, and this plays a very important part. The ewes should be in good condition when mated and kept so right up to lambing time, and if sufficient feed is not available in the paddocks hand-feeding should be resorted to. A couple of stubble paddocks should be seeded with a combine in the early autumn with fodders for feed. A good mixture is 40 lbs. of barley, 2lbs. Giant Kangaroo rape, and 50lbs. of super to the acre for one paddock, and 40lbs. of Mulga oats, 2lbs. of Wimmera Rye Grass, and 50lbs. of super to the acre for the other, especially if the latter one is to be left out for three or four years, as the Wimmera Rye Grass will give good grazing during this period.

Any sheepman knows that sheep do better if changed often on to fresh and different kinds of feeds, and this holds good in growing fat lambs. Having paddocks reasonably small helps considerably to this end.

Every farmer on the cleared areas of southern Eyre's Peninsula, especially from Lock south, should breed some fat lambs. The freezers at Port Lincoln are conducted for the benefit of primary producers, and as Mr. McCann (the Trade Commissioner) informed local settlers, the lambs exported to Britain from Port Lincoln were now a wonderful colour and a credit to the producers, and it is up to sheep breeders to patronise the freezers more, as the greater the number of lambs sent in so will the overhead expenses of exporting them be smaller. Further, the money received from fat lambs is particularly helpful as it comes at a time when other returns from the farm are small.

HANDLING THE LAMBS.

After growing the lambs a very important thing is the correct handling of them. If they are to be drafted from the flock through a race great care should be taken not to jam the lambs with the gate, and sticks should not be used to poke them through. A great number of lambs are badly bruised by rough handling during drafting. If no drafting race is available the lambs should be caught by putting

the arms around them at the brisket when they can be lifted easily without any chance of bruising or injuring them in any way. A lamb should never be caught by the wool or by a leg, as the former will always bruise, and the latter may seriously injure the animal. Bruised or injured lambs mean rejects at the slaughterhouse and consequently less money returns, and so careful handling is a paying proposition.

CONCLUSIONS.

1. Have good, roomy ewes as breeders.
2. Select only the best type of rams as sires.
3. Grow plenty of feed.
4. Feed the sheep well.
5. Change the sheep from paddock to paddock frequently.
6. Always handle lambs carefully.

Close adherence to these rules *must* lead to success.

SOME PREVENTABLE DISEASES OF PIGS.

[Paper read by A. H. Robin, B.V.Sc. (Government Veterinary Officer), at the Forty-fifth Congress of the Agricultural Bureau.]

A tremendous number of young pigs that are born never survive to reach the market, and the loss of animals through disease is the greatest factor militating against profitable pig raising. In this paper, some of the diseases that frequently cause heavy losses in this State are dealt with.

DIARRHOEA OR WHITE SCOUR.

Suckling pigs a few days old frequently become affected with a form of diarrhoea or white scour which results in their death within a day or two of its onset or, if the little pigs survive, causes them to receive a severe setback in their growth.

One of the most common causes of this trouble is too generous feeding of the sow prior to and immediately after farrowing, as the result of which the little pigs get more milk than their digestive organs can deal with. Sudden changes in the sow's diet will cause it, as also will the existence of insanitary conditions in the sties as the result of which, through contamination of the sow's udder, countless filth organisms are swallowed down by the youngsters when suckling.

The prevention of the trouble consists in proper management of the sow and keeping the sties in a clean and sanitary condition. The sow should not be permitted to get into fat condition, and while her diet should be sufficient and varied with due proportion of flesh and bone forming elements, it should not contain excessive amounts of protein. The feeding of protein should be reduced for a week or ten days prior to farrowing, and when the sow has been put into the pen in readiness for that event, her diet should be laxative in character. No food should be given for 24 hours after farrowing, though water *ad lib* should be provided. Subsequently the feed given should be light for a day or two and then gradually increased during the next 7 to 10 days after which a full ration can be fed. Sudden changes in the diet should be avoided. The sty should be kept clean and the sow's udder as free as possible from contamination by filth.

Treatment of the trouble when it occurs consists of reducing the feeding of the sow for a few days and giving the affected suckers each a teaspoonful of castor or olive oil. The sow's udder can be smeared with a solution of citrate of iron or the following mixture given to the suckers:—Sulphate of iron, 3 drams; sulphate of copper, 1 dram; water, 1 pint. Dose, 1 teaspoonful. Turning the sow and litter out on to pasture during portion of the day will often prove beneficial in checking the trouble.

NUTRITIONAL ANAEMIA OF SUCKLING PIGS.

It not infrequently happens that suckling pigs when confined all the time to sties while living exclusively on their mother's milk, suddenly at the age of 3 to 4 weeks, start to "go back," although previously they appeared to be thriving quite normally. They become pale and listless, sudden deaths may occur among them, or instead of growing on as they should, they become stunted, unhealthy and short of breath. More or less severe diarrhoea or scour often supervenes, the skin becomes mottled and unhealthy in appearance and death not infrequently results after the little animals have become emaciated and miserable looking.

This trouble is one of anaemia due to a lack of iron, and it is more particularly likely to arise if the sow throughout her pregnancy has been confined to the sty and inadequately fed.

Its prevention lies in suitable management of the sow while "in pig" and of the sow and litter after farrowing. Normally the embryo pig, during the process of its development "in utero," stores in its liver a supply of iron received from the mother in order to meet its requirements for this mineral during the suckling period, as sow's milk is almost lacking in the iron that is so necessary for the formation of blood in the young growing pig. If the sow is kept continuously confined to the sty during pregnancy and is deprived of the opportunity of obtaining iron from the soil or from green feed, there is every possibility that she will not be able to hand on to the embryonic pigs a supply sufficient for their requirements. She should therefore be allowed regular access to pasture so that she can obtain ample supplies of this mineral or if she has to be kept confined, be given a regular allowance of green feed as well as a supply of ashes and earth. Subsequently after farrowing has taken place, access to clean pastures for at least 2 or 3 hours daily should be afforded to both her and her litter from the time that the little pigs are 10 days old.

Should this trouble make its appearance in any litter of young pigs, the simplest and most effective curative treatment is to turn the sow and her pigs out on to clean pasture immediately. The young pigs will at once begin to root in the earth and eat it and in this way obtain the necessary supplies of iron to restore them to health. The trouble can also be dealt with by drug treatment, giving the young pigs 1 dram doses of Parrish's Food daily for 2 or 3 days, or 3 to 6 grains of either Ferri Carb. Sacch., or Ferri Ammon. Cit., but the individual dosing of a number of young pigs daily is a troublesome and less practical matter.

CONTAGIOUS PNEUMONIA (SWINE PLAGUE).

Outbreaks of a highly infectious form of pneumonia occur at times in piggeries, occasioning heavy mortalities among the animals. The organism responsible is the *Bacillus suisepticus*, which is quite a common inhabitant of the lung tissues of apparently healthy pigs and becomes activated as the result of some sudden lowering of the animal's vitality. Exposure to cold draughts, wet weather, irregular feeding, sudden changes of diet, and the transportation of the animals from one place to another are all factors that may act as predisposing causes, reducing the vitality of the animals and enabling the organism to set up the disease if present in the lungs. Accordingly, pigs which have been exposed in the saleyards and have to contend with such factors as those mentioned are particularly liable to contract the disease and spread it in a virulent form when introduced into fresh premises.

The symptoms of contagious pneumonia vary. In very acute cases the animals show high fever, loss of appetite, staggering gait, respiratory distress, and death occurs in 12 to 24 hours. In less acute cases, the animals survive longer, showing all the signs of acute pneumonia, viz., laboured breathing, cough, nasal discharge, and depression. Red blotching of the skin occurs and sometimes diarrhoea. Examination of a pig dead of the disease may show very little beyond numerous small haemorrhages throughout the body, if death supervened within a few hours. In cases where the animal was ill for longer than 24 hours, solid dark-coloured areas in the lungs are always present and the lining of the stomach and small intestines may be red and inflamed.

The prevention of this disease is largely a matter of maintaining good hygiene and sanitation of the pig premises—the animals' quarters should be dry, clean, warm, and free from draughts, and they should be regularly fed.

Particular care should always be taken to isolate newly purchased pigs for 10 to 14 days to make sure that they are not affected with the trouble. Nothing can be done in the treatment of affected animals, though all such should be isolated immediately they are noticed sick. Carcasses of dead animals should be effectively disposed of.

The disease is a notifiable one under the Stock Diseases Act, South Australia, and, on its occurrence or suspected occurrence, the nearest Stock Inspector or the Chief Inspector of Stock, Adelaide, must be immediately notified. A history of a number of animals being affected with pneumonia following the introduction of newly purchased pigs is very suggestive.

LICE.

Infestation with lice (*Haematopinus Suis*) is a very prevalent trouble in pigs in this State and should be controlled more than it often is. This pig parasite is the largest of all animal lice and causes intense irritation to animals infested with it, resulting in their losing condition seriously and suffering from various forms of skin trouble, such as eczema, &c. It is a blood sucker and the vitality of the pigs is often so reduced that they fall prey to other diseases of a fatal nature. Dark, dirty sheds and sties and badly drained yards are favourite breeding grounds for the parasite.

There is no difficulty in detecting the lice on inspection of the animals, favourite sites on the body being the grooves or folds of skin behind the ears and on the inner surface of the hind legs.

Treatment consists of the application of dressings to the pig's skin for the destruction of the lice and nits and the cleaning up of the sheds and sties. Where large numbers of animals have to be dealt with, they can be put through a dip in the same manner as sheep are dealt with. Any non-poisonous sheep dip preparation can be used, or solutions of any of the coal tar derivatives such as lysol, creolin, &c. The strength of the solution should be ½ per cent. or 1gall. of dip preparation to 50galls. of water.

A preparation of kerosene, 2ozs., raw linseed oil, 1 pint, can be used to dress the pigs, applying the mixture with a brush or cloth, or kerosene emulsion may be used. This is prepared by cutting up 8ozs. of soap and dissolving it in hot water. When boiling, stir in well 2galls. of kerosene and keep stirring until the solution is cool. Add 1gall. of this emulsion to 8galls. of water and spray or wash the animals with it. The only precaution to take in using these mixtures containing kerosene is not to apply them during the heat of the day, else the pigs are liable to be scalded. Apply them in the cool of the evening.

Waste engine oil is also a very effective dressing. One of the simplest ways of dealing with the parasite is to allow the pigs to oil themselves by providing them with a rubbing post, wrapped round with sacking which is kept soaked with the oil. The pigs will scratch themselves on the post and the oil will thus saturate the hair and destroy the lice.

All infested sties and sheds should be thoroughly cleansed, disinfected, and lime washed, and all litter, bedding, and manure burned.

ASCARIASIS OR ROUND WORM INFESTATION.

The Round worm *Ascaris lumbricoides* (*Suilla*) is undoubtedly the most widespread and serious trouble met with in pigs in this State. While older animals are much more resistant to infestation with it, this parasite is particularly injurious to young pigs up to the age of about 4 months, and not only does it cause the deaths of large numbers of them here every year, but a great many more that do not actually succumb to the infestation have their growth so retarded that it is impossible for them to be got into marketable condition sufficiently quickly to make them at all profitable to their owners.

Because of the serious losses it causes to pig raisers here, I have devoted a considerable portion of this paper to dealing with it.

The adult worm is from 6in. to 12in. in length and from $\frac{1}{8}$in. to $\frac{1}{4}$in. in diameter, and is whitish in colour and pointed at both ends. Its habitat is the small intestine of the pig, and here at times hundreds of them may be found present. Occasionally it may be found in the stomach or invading the bile ducts of the liver.

Pigs become infested through ingestion (or swallowing) of eggs containing infective embryo worms. Young sucking pigs frequently swallow such eggs which become adherent with dirt, &c., to the sow's udder; older pigs usually swallow them along with the food and drinking water.

The life history of the *Ascaris* is a remarkable and particularly interesting one, and is well worth pig owners understanding it. Briefly, it is as follows:— The eggs are laid in the pig's intestine by the mature female worm, and are passed out with the animal's dung. They are not infective immediately they leave the animal, but require up to several weeks lying on the moist warm ground to "ripen" or develop into this stage, when a tiny embryo worm has developed inside the shell. These embryos do not hatch out of the shell until the eggs are swallowed by susceptible animals, and the eggs are particularly resistant to unfavourable climatic conditions (such as drought, frost, &c.) and to strong disinfectant solutions, and can remain dormant on the ground for, it is stated, as long as 5 to 7 years and then still be capable of developing into adult worms if swallowed by pigs.

When the "ripe" or infective egg is swallowed the shell is dissolved in the pig's intestine and the embryo worms set free. Then a remarkable migration takes place. They at once burrow into the intestinal wall, and so reach the blood and lymphatic streams in which they are carried, first to the liver and from there, shortly afterwards, to the lungs where they leave the blood stream and pass through the lung tissues into the windpipe, where they undergo some further development. The time taken for the embryos to reach the windpipe after the eggs are first swallowed is usually about 8 to 10 days, though they have been found there as early as 3 days later. It is during this migration of the embryos through the lung tissue and while they are located in the windpipe that infected pigs suffer from coughing, bronchitis, and, not infrequently, pneumonia.

From the windpipe, the young larvae either crawl up or are coughed up into the pig's mouth. They are then swallowed again and so eventually return to the intestine where they develop into the adult stage, which is attained 7 weeks or more after the first swallowing of the eggs.

The clinical symptoms set up in infested animals are somewhat variable owing to the complex life history of the parasite, but the following are the most important:—

(*a*) Young pigs (before or shortly after weaning) will frequently contract a severe and rapidly fatal pneumonia, with symptoms of listlessness, lack of appetite, cough, and difficult breathing—death resulting in from one to several days. Where the degree of infestation is less heavy, the course of their illness is more chronic—the animals do not eat well, lose condition, and become weak and stunted in growth. Fits of coughing are most pronounced. Death may take place within a few weeks or occasionally the coughing may gradually disappear, leaving the animal with a difficult or "thumpy" breathing.

(*b*) Older pigs (weaned a month or two) may sometimes develop the rapidly fatal pneumonia described above (*a*), though more commonly they show the more chronic type of illness. Again, in others, the symptoms may be less definite—the animals failing to "grow on," becoming pot-bellied and thin and weak despite good feeding. Convulsive fits while or shortly after feeding are not uncommon.

(*c*) Older pigs are much more resistant to infestation with the *Ascaris*, harbour fewer worms, and suffer less from the invasion of them, showing nothing more than perhaps some degree of general unthriftiness with an occasional slight cough.

Control Measures.

It is the little pigs up to approximately 4 months old that especially require protection from the *Ascaris*. The measures necessary to afford them this comprise:—

(1) Systematic medicinal treatment of infested animals; and

(2) The establishment of satisfactory sanitary measures to prevent, as far as possible, the animals from swallowing infective eggs lying on the ground, floors of sties, &c.

Many different remedies are tried by pig owners for treatment of infested animals, but most of these are of little or no value or are uncertain. Mass dosage of the animals by mixing in with the food enough of the medicine for a number of pigs is, moreover, the system of dosing usually adopted, but the disadvantages of this style of treatment are obvious, and usually the most heavily-infested animals, owing to their weak condition, will get little or none of the medicine. The only satisfactory way of carrying out the work is by dosing each animal separately—it is certainly rather more laborious, but is infinitely more successful and worth while. Two men, one holding the pig while the other one doses it, should easily be able to get through the job at the rate of a pig per minute.

The most effective and economical drug is Oil of Chenopodium, and the following table sets out doses that are safe and effective:—

Age.	Dose.
	Minims.
8 weeks	20
10 weeks	25
12 weeks	30
14 weeks	35
16 weeks	40
	Fluid Drams.
6 months	1
9 months	1½
12 months and over	2

(1 minim = 1 drop; 1 fluid dram = 1 teaspoonful.)

The dose of Chenopodium is added to a full purgative dose of Castor or Raw Linseed Oil—the dose of either of these being from 1-4 fluid ounces (2 tablespoonsful = 1 fluid ounce) according to size of pig. The mixture is then well shaken up with a little milk, and the whole given as a drench.

The pigs must be starved for 24 hours prior to dosing, and as soon as the purgative has acted they may be given their usual food and water. It should hardly be necessary to point out that they should be keep confined until the medicine has acted so that all worms and manure voided can be collected and properly disposed of.

While dosing the animals will remove most, if not all, the worms they are harbouring, re-infestation of them will promptly take place again if they are allowed to return to egg-contaminated pastures or other quarters. The young pigs should therefore, after dosing, be either removed to a part of the farm where pigs have not previously been running, or if this is impracticable they should be put into clean sties that can be kept regularly and thoroughly cleaned out. These sties should therefore have hard floors of flat stone, bricks, or concrete. If these floors and also the food and water troughs are thoroughly cleaned out every 10-14 days

by the use of water and a hard stable broom, any worm eggs that may happen to be deposited thereon will be removed before they can mature or develop into the infective stage, and in consequence the young pigs will not become re-infested.

If these control measures outlined are carried out, owners who have been experiencing serious trouble and losses in their animals, due to the round worm, will find that these difficulties will very largely disappear so that their work of pig raising can be carried on much more successfully.

A system of control to which I would draw the attention of pig raisers in this State is that known as the McLean County System of Swine Sanitation. This system was evolved by the veterinary staff of the United States Bureau of Animal Industry and thoroughly tested out on a number of farms in the McLean county of Illinois, and it proved so successful in preventing losses from worms that its employment has spread rapidly and continues to do so. There is no reason apparent why it cannot be employed on many farms in this State where *Ascarid* infection is troublesome. The system consists, in essence, of so handling young pigs from the time of birth until the age of several months (that is, during the most susceptible period of their lives) that the chances of their becoming infested is reduced to a minimum.

Two essentials are necessary to the scheme, viz., properly constructed farrowing pens and fresh, clean pastures. The farrowing pens should have impervious floors and walls so that they can be kept thoroughly cleaned, and they should be so situated that it is not possible for drainage from other pigs' quarters to contaminate them. Each time prior to their being used for farrowing purposes, all litter is removed and the floors and walls thoroughly scrubbed with boiling water and washing soda to remove dirt and destroy any worm eggs.

Three or four days before they are due to farrow, the sows have all loose mud and dirt removed from their skins by thorough brushing, and their udders and feet thoroughly washed with soap and warm water. They are then placed in the clean pens. This preliminary cleansing prevents the sows from carrying into the pens perhaps millions of worm eggs picked up with the soil of the pig yards and which the young pigs would be most likely to swallow during the process of suckling.

The sows and their litters are not allowed out of these pens until they are removed to the clean pastures, which is done about 10 days after farrowing. In carrying out this transfer, it is essential that the animals be moved on a specially-constructed sledge or other conveyance; they must not be permitted to walk over ground that has been soiled by other pigs.

The special pasture should be one that has not previously been used for running pigs on; it should be so fenced that the little pigs cannot get out and find their way to other pig paddocks, and no other pigs should be allowed access to it. Its location will depend on the facilities afforded by the farm, but to avoid accidents the further away it can be from the permanent pig runs the better. Water, feed and shelter must, of course, be provided on it for the sows and young pigs and, if possible, each sow and her litter should be kept separate.

The young pigs are kept on this clean pasture until they are at least 4 months old, after which age they are not very highly susceptible to suffer from worm infestation, even though they then be exposed to it. They can then be removed to other paddocks or direct to the finishing pens.

Summarising the system, the steps to be carried out are:—

(1) Remove all litter and thoroughly clean out the farrowing pens with hot water and washing soda.

(2) Three or four days before farrowing, scrub the sow thoroughly with a brush, using soap and warm water to cleanse the udder and feet. Put the sow in the clean pen.

(3) Ten days after farrowing haul—do not drive on the hoof—the sow and her pigs direct from the pen to the clean pasture.
(4) Keep other pigs away from this pasture and the sow and little pigs away from other dirty pig paddocks.
(5) Leave the young pigs on the clean pasture until they are at least 4 months old.

It is advisable to dose the sows with Chenopodium some time when not in farrow so as to get rid of any worms they might be harbouring.

These requirements are quite simple, but each and every one of them is important. Carefully carried out in detail, they will not only enable losses in young pigs from *Ascarids* to be avoided, but they will enable better pigs to be raised. It is interesting to note the records compiled from 154 farms in Illinois, U.S.A., where this system of sanitation was adopted. These showed that apart from the avoidance of losses in numbers due to *Ascarid* infestation, the young pigs were ready for market 7 weeks younger than the usual market age under previous methods of control, and that when 4 months old the pigs raised weighed 28lbs. more on the average than other pigs on the same farms not raised under the system.

MINERALS FOR PIGS.

Mineral matter is of the greatest importance to young growing pigs, being required for the maintenance of vital body functions and the growth of sound bone. It also assists in the building up of the food proteins into muscular and other body tissues. A deficiency of it leads to unthriftiness, poor development, and the occurrence of diseases such as depraved appetite, paralysis, and rickets. So if they are to remain healthy and make rapid growth their diet must contain supplies of it ample for their needs While all feeding stuffs contain various minerals required by pigs, the amounts present vary considerably, *e.g.*, some foods are rich in Calcium, others are poor in it, &c. Should there be any danger, therefore, of the ration supplied being short to any serious extent of the animals' requirements of them, then a mineral supplement should be fed in order to make good the deficiency.

From the practical feeder's point of view the trouble is to know when and in what respects the ration he is feeding to his pigs is likely to be deficient in minerals, and what and how much of mineral supplements he should feed. During recent years the mineral requirements of pigs have received considerable attention from research workers in many countries, and a vast amount of information has been obtained on the subject, from which it is possible to advise on these several points briefly as follows:—

1. The only mineral constituents that are ever likely to be lacking to any serious extent in rations fed ordinarily to pigs from weaning to marketing condition are Calcium (Lime), Phosphates, and Common Salt (Na Cl).

2. Separated milk is rich in all of these, and if the ration includes it to the extent of about ½gall. per pig daily the supply of minerals will be ample, and no mineral supplement need be fed.

3. Cereals and their by-products and vegetable cakes are seriously lacking in Calcium (Lime), though rich in Phosphates; roots and tubers (potatoes, swedes, &c.) are deficient both in Calcium and Phosphates. All of these foods have a low content of Common Salt.

If the major portion of the ration consists of cereals and their by-products, and separated milk is not included, the ration is likely to be deficient in Calcium and Salt, and Salt and a Calcium-rich supplement should be fed.

If roots and tubers are extensively fed, the mineral supplement should contain Phosphates as well.

4. Calcium (lime) may be supplied either in the form of a phosphate (bone meal, dicalcic phosphate), or as ground limestone (calc. carbonate), or agricultural lime.

When cereals predominate in the ration, the latter forms give equally good, if not better, results than the phosphate forms.

Two per cent. of any of the above added to the ration will be ample. Common salt may be fed at the rate of ⅛oz. to ¼oz. per pig daily.

5. If it is desired to provide the necessary minerals in the form of a mixture, either of the two following will fully supply the need:—

(*a*) Ground limestone or agricultural lime, 2 parts; common salt, ½ part—2½ per cent. added to the food.

(*b*) Ground limestone or agricultural lime, 1 part; bonemeal or dicalcic phosphate, 1 part; common salt, ½ part—2½ per cent. added to the food.

If roots and tubers are extensively fed, the latter mixture is preferable. It is also the preferable mixture for brood sows, for which the quantity given should be increased to 3 or 4 per cent.

6. There is no advantage to be gained from the addition of iron, sulphur, iodine, &c., to mineral mixtures for pigs.

It is necessary to point out, in conclusion, that an adequacy of minerals in the diet of growing pigs is not of itself sufficient to ensure good results; the animals must also have conditions whereby they can utilise the minerals. This necessitates their obtaining a liberal supply of Vitamin D—the anti-rachitic factor that controls the assimilation of minerals and an absence of which will cause unthriftiness, paralysis, and rickets to develop, even though minerals be abundantly present. Sunlight is the most potent (and also the cheapest) supplier of this essential vitamin, and pigs running out in the open and exposed to it will, of course, receive all they require of it. If, however, they are confined to sties, these should be so constructed that they will let in plenty of sunlight. Green feed is also well supplied with Vitamin D and can advantageously be fed.

ANNUAL REPORT ON PASTURE WORK, KYBYBOLITE, 1933-34.

[By L. J. Cook, R.D.A., Manager.]

A comparatively good pasture season was experienced during 1933-34, and of 524 acres of fields and plots that have been used as permanent pasture during recent seasons, 258 acres (49 per cent.) of them recorded increased carrying capacity over the previous season, and the majority of the other fields exceeded the average for the past six seasons. Consequently a further increased number of livestock was carried on the Farm for the year.

Throughout the agricultural year, April 1st, 1933, to March 31st, 1934, an average of 1,626 sheep and 143 cattle have been kept, as against 1,460 sheep and 127 cattle during the previous 12 months, showing an increase of 166 sheep and 16 cattle. Approximately 236 acres of temporary pasture were available during the season, and 147 acres were sown to crops. Hence 760 acres pasture, with the stubble feed of 147 acres, have provided feed for 1,626 sheep and approximately 81 head of growing cattle wholly throughout the season, as well as provide full pasturage for 49 milking cows during the pasture growing period, and portion of their feed during the balance of the year. Also 25 horses have had part-time grazing. Besides above grazing 83 tons pasture growths were cut for silage making, and 22 tons meadow hay were made and stored from various fields. One hundred and ten acres of the general pasture fields were not top dressed this season, and another 100 acres received only ½cwt. application per acre. Naturally the quantity and quality of feed was less through this shortage of top dressing, but sufficient was available for the above livestock on the Farm.

The Season.

The season commenced well, a good germinating rain being received during the first week of March, which was followed by showery conditions in that month. About middle of April, a very fine rain of over 2in. gave the pasture plants really good vigour. This was followed by 5in., well distributed throughout the month of May, causing an exceptionally fine growth of pasture plants for the winter months. June and July produced mild conditions with only light rains, so that no trouble was caused by excessive wet conditions. Very good falls were recorded during August, September, and early October, enabling plenty of early spring growth to be made. A setback was then received from a dry, comparatively warm period of six weeks, which caused plants to run to maturity rather quickly.

Very good rains were received during the third week of November, but these were really too late to give a lot of benefit to the pastures, and caused a reduction in the quality of the meadow hay, which was being cured in the fields at the time. Summer rains were below average, but plenty of dry feed was available in the paddocks to carry the stock along until the break of the season in 1934. Altogether 22.30in. of rain fell during the agricultural year, which was 60 points in excess of the average for the past 28 seasons.

The following table shows the monthly rainfall of recent years compared with the average for the past 28 seasons:—

	1926.	1927.	1928.	1929.	1930.	1931.	1932.	1933.	1906-33.

IMPROVEMENT OF NATURAL PASTURES WITHOUT CULTIVATION.

The work of top dressing natural pastures with phosphatic fertilisers and lime was commenced in 1919, additional plots have been added from time to time, and at present there are 13 plots being used for this work, nine of which are 3½ acres in area, and four are 5 acres each. Since 1921 careful records of the grazing secured from the plots have been kept. For the past five seasons the plots have been continuously grazed in rotation by four flocks, constituted according to the estimated carrying capacity, and a separate flock has been used for each type of fertilised pasture. That is: A flock, 12 sheep, has been used on unmanured land, 13½ acres; B flock of 35 sheep has been used on 14 acres of land improved with superphosphate; C flock of 48 sheep has been used on 17 acres of land improved with lime and superphosphate; while D flock of 20 sheep has been used on 10½ acres of land improved with rock phosphates. Another small flock has been used on all fertilised plots as required to utilise excess feed. Similar type and aged sheep have been used in each flock, constituted of 25 per cent. Waite Institute Merino wethers and 75 per cent. Kybybolite Comeback ewes.

Through the assistance of the Waite Research Institute we have been able to weigh these sheep monthly, and so keep a definite record of their development on this type of pasture.

This season further consideration has been given to the botanical analysis of these pastures, and once per month throughout the growing period percentage estimates were made by taking six indiscriminate quadrat readings over each plot.

The following table shows the fertiliser applied, with date and rate of applications, whilst Table 3 shows the grazing results secured.

TABLE 2.—*Fertilising of Natural Grazing Test, Kybybolite,* 1919-34.

Plot.	Total Fertiliser per Acre.	Date and Rate of Application.
6	No manure (check plot)	—
12	No manure (check plot)	—
1	1 ton Aluminium Phosphate Rock (412lbs. phosphoric acid)	1919, one application
4	11cwts. Calcium Phosphate Rock (232lbs. Phos. acid) .	1919, one application
	6cwts. Clacium Phosphate Rock (127lbs. Phos. Acid) ..	1920-25, 1cwt. per annum

											0·33		

The return in quantity of growth from these plots, as shown by the sheep carried per acre, is continuing to increase. The average return for all fertilised plots in the series has been 3.14 sheep per acre for the season, which is the highest return so far received, and is ¾ sheep per acre above the average secured for the past 13 seasons. It is significant that all plots on which the application of fertiliser has been maintained have yielded in excess of their averages, whilst only four, namely, the two check plots Nos. 6 and 12, that have never been fertilised, and Nos. 1 and 11 that were top dressed with rock phosphate 14 and nine years ago respectively, have yielded returns below their averages.

Four plots yielded their best return since commencement, namely—No. 3, fertilised with lime and superphosphate carried 4.59 sheep per acre, a record for this type of pasture; No. 8 fertilised with 180lbs. superphosphate carried 4.26 sheep, which is also a record for superphosphate on this type of pasture; No. 13 fertilised with limestone and superphosphate carried 3.83 sheep, a slight increase on the previous season; and No. 2 fertilised with 51lbs. superphosphate carried 3.51 sheep, which is considerably better than the average secured from this plot.

For the season the three plots dressed with lime and superphosphate have averaged 3.77 sheep per acre, and the three plots dressed with superphosphate only have averaged 3.78 sheep, practically no difference, whilst the two plots, Nos. 4 and 5, that have received continued applications of rock phosphate carried 2.70 sheep, approximately one per acre less.

The same plots averaged over the immediate past eight seasons have carried 3.11, 2.78, and 2.10 sheep per acre per annum respectively, showing an increase of 0.33 (12 per cent.) sheep for lime and superphosphate over superphosphate only; 1.01 (48 per cent.) sheep for lime and superphosphate over rock phosphate; and 0.68 (32 per cent.) sheep for superphosphate over rock phosphate.

Compared with the check plots (no manure) the same three series of plots have shown increases of 2.22 (249 per cent.), 1.89 (212 per cent.), and 1.21 (146 per cent.) sheep per acre per annum for the eight seasons.

It is noted that the plots dressed only with superphosphate have become as productive during recent years as those dressed with lime and superphosphate. Rock phosphate dressed plots maintain a production intermediate between the lime and superphosphate dressed plots and the check plots.

In the following table the averages of all plots for the past eight seasons have been grouped together according to the various forms of fertiliser, and shows an interesting comparison of returns and value.

TABLE 4.—*Comparative Summary of Eight Years' Grazing on Topdressed Natural Pasture.*

Fertilisers Applied.	Area.	Sheep per Acre.	Increase over no Manure.	Increase over Superphosphate.	Increase over Rock Phosphate.	Annual Cost of Fertiliser per Acre.	Annual Cost of Fertiliser per Sheep.	Profit per Acre per Annum, Sheep at 15s.
	Acres.		%	%	%	*s. d.*	*s. d.*	*s. d.*
Lime and Superphosphate (W.S.P.)	8½	3·14	253	13	50	11 0	4 11	22 9
Crushed limestone and Superphosphate (W.S.P.)	5	2·91	227	4·7	39	8 3	4 1	22 1
Superphosphate (W.S.P.)	8½	2·78	212	—	32	5 8	3 0	22 8
Gypsum and Superphosphate (W.S.P.)	3½	2·54	185	—	21	10 9	6 6	14 0
Ephos Phosphate (Cit. and Acid Sol. Phos.)	5	2·11	137	—	0·5	6 0	4 11	12 4
Crushed Rock Phosphate (A.S.P.)	10½	2·10	136	—	—	4 2	3 5	14 0
No manure (Check plots)	8½	0·89	—	—	—	—	—	—

This table shows that when sheep are valued at 15s. each per annum the profit obtained due to fertiliser has been approximately the same from the use of superphosphate only and from lime and superphosphate combined. The cost of superphosphate dressings has been 5s. 8d. per acre, or 3s. per sheep, whilst that of superphosphate and lime combined has been 11s. per acre, or 4s. 11d. per sheep. The extra sheep carried on the lime and superphosphate plots has only covered costs.

Crushed limestone and superphosphate combined shows a profit of 22s. 1d. per acre per annum, only 8d. less than the burnt lime and superphosphate, whilst gypsum and superphosphate combined and Ephos phosphate have returned much lower profits with 14s. and 12s. 4d. per acre respectively.

Rock phosphate, with its low annual cost of 4s. 2d. per acre, has returned 14s. per acre profit.

With reference to the type and variety of plants growing on these series of plots, the monthly estimations taken throughout the growing period this season have been averaged, and are shown in the following table.

TABLE 5.—*Botanical Analysis of Natural Pasture Plots, Kybybolite, 1933.*

Species.	Rock Phosphate Plots.	Superphosphate Plots.	Lime and Superphosphate Plots.	Average all Fertilised Plots.	Check Plots. No Manure.
	%	%	%	%	%
Grasses	65·45	68·58	67·99	67·79	44·87
Clovers	16·23	19·75	10·07	14·50	0·18
Erodium	0·96	1·78	7·04	3·16	Trace
Thistles	0·08	0·68	2·32	1·00	0·35
Capeweed	0·12	0·65	1·49	0·68	0·12
Miscellaneous	12·39	6·64	7·95	9·22	29·76
Bare space	4·76	1·91	3·12	3·63	24·72

Factors of note from this table are that the percentage of grass on all fertilised plots was comparatively constant, varying only from 65 per cent. on rock phosphate plots to 68 per cent. on superphosphate plots, whereas the amount of grass on unmanured plots was only 45 per cent. Naturalised clovers varied from 10 per cent. on lime and superphosphate to 20 per cent. on superphosphate only plots, compared with only 0.18 per cent. on no manure plots. It is perhaps significant that erodium has increased to 7 per cent. on the lime and superphosphate plots, whilst only 1 to 2 per cent. has been recorded on other fertilised plots, and it is scarcely present on check plots. Also thistles and cape weed are more plentiful on the lime and superphosphate land. The amount of miscellaneous or useless growths are more numerous on the check plots, close upon 30 per cent., and rock phosphate dressed plots 12 per cent., whereas the better fertilised land has reduced these growths to 6 and 8 per cent. Similarly the amount of bare space is very much greater on the unmanured land, approximating 25 per cent. against 2, 3 and 5 per cent. respectively.

Time would not permit to fully analyse the various grasses that grow on the plots, but each autumn counts and measurements were made of the Danthonia (native Wallaby grass) plants by reading six indiscriminate square metres on each plot. On averaging the growths of the last two autumns, the number and size of plants per square metre on the various fertilisings are as follows:—

	Number of Plants.	Diameter in Inches at Ground Level.
Check plots (no manure)	109	0.82
Rock phosphate dressed plots	59	1.39
Superphosphate dressed plots	32	1.56
Lime and superphosphate dressed plots	24	1.32

This work shows that the fertilising has apparently depressed the number of permanent native grass roots, but at the same time has increased the vigour of those that have survived.

In considering the behaviour of sheep flocks used for grazing these natural pasture plots, the following table shows the average live weight of Comeback ewes, the average weight of wool, percentage of lambs marked, average weight of lambs at weaning, and the sheep carried per acre for each of the four flocks during the past four seasons.

TABLE 6.—*Weight of Sheep and Wool, Natural Pasture Plots,* 1930-34.

Flock.	No. of Ewes.	Kind of Fertiliser on Plots.	Average Weight of Ewes.			Average Weight of Wool per Sheep.				Lambs Marked.			Average Weight of Lambs at Weaning.			Sheep Carried per Acre.

			30/3/32	84·3	89·4	25/10/32	9	7		1/10/32	93		17/1/33	53·5		1932-3	2·13	
			31/3/33	89·6		12/10/33	7	9		1/10/33	71		4/1/34	59·9		1933-4	2·28	
			31/3/34	97·4														

All of the ewes in the above flocks are of similar age and breeding (1928 spring drop), and were selected as even in type and development in May, 1929. Since then they have been kept wholly on the one class of pasture. Except for a few weeks in the autumn of each season, when the 86 ewes were mated together as one flock with Merino rams, they have been pastured on the respective plots, fertilised as shown in the table. They have received no hand-feeding, nor provided with any licks.

The average live weights of ewes quoted are those taken about the close of March each season, a time when their weights were lowest. During each season of growing pasture, the ewes increased in weight, and during each late summer and autumn they decreased in weight.

The average maximum weights attained by the four flocks for the four seasons, which occurred in the late spring were:—

	Lbs.
Flock A	107.4
Flock B	116.7
Flock C	120.4
Flock D	104 5

When these are compared with the autumn weights given in Table 6, it is seen that the average difference between the maximum and minimum weights of each flocks has been:—

	Lbs.	Variation. Per Cent.
Flock A	14.4	13.4
Flock B	22.4	19.2
Flock C	24.1	20.0
Flock D	15.1	14.4

Hence the ewes pasturing on the natural pasture, that has been fertilised with superphosphate only, and with lime and superphosphate combined, have shown that they reached much higher live weights during the flush parts of the seasons, but also lost considerably more pounds in weight during the leaner grazing periods. At all times, however, they maintained a greater average weight than those on unfertilised pasture. Those on pasture fertilised with both lime and superphosphate have maintained slightly better weights than those on pasture fertilised only with superphosphate, especially during the last two seasons.

As regards the wool production the figures in the table show that there has been no material difference between the flocks. There has been a difference of only 4ozs. per head between the highest and lowest average—8lbs. 2ozs. per head from Flocks A and C, 8lbs. 5ozs. from Flock B, and 8lbs. 6ozs. from Flock D.

The lambing percentages, however, show a distinct difference, those on the lime and superphosphate pasture yielding an average of 84 per cent. over the four seasons, as against only 64 per cent. from the flock on unmanured pasture, the former producing the highest percentage of the four flocks in two seasons, 1930 and 1933, whilst D flock on rock phosphate fertilised pasture gave the highest percentage in the other two seasons, 1931 and 1932. Both B and D flocks, with 76 per cent. and 79 per cent. averages, were considerably better breeders than A flock.

The weights of lambs at weaning show that those from the A flock to have been the heavier lambs. This is due entirely to the different summer feed available during December on the unfertilised pasture. The fertilised pastures at this time of the year contain a large proportion of dry annual grasses, such as barley and silver grasses, with their objectionable seed

heads, which have proved detrimental to the lambs. It is definitely not due to the strength of the lambs, as the lambs in B and C flocks have invariably been stronger from birth, and for the four seasons averaged 3lbs. greater in weight during October months, than those on the unmanured pasture.

It must be noted that to supplement the amount of unfertilised feed, Plot No. 9 in unmanured clover land series has necessarily had to be used at times by Flock A, which accounts for the carrying capacity of plots grazed showing at 1.04 sheep per annum, which is higher than unfertilised virgin land, and should, if anything, give the flock an advantage.

Regarding the losses of sheep that have occurred amongst these flocks, four ewes of the original 87 have died, two in Flock B, and two in Flock D. Of the former one died as a hogget in 1929, and the other died at four years of age in 1932. The two ewes in Flock D both died in 1933 at five years of age. The annual percentage loss of ewes over the five seasons for each flock has therefore been as follows:—

		Per Cent.
Flock A (9 ewes)	Nil	
Flock B (27 ewes)	2 deaths	1.48
Flock C (36 ewes)	Nil	
Flock D (15 ewes)	2 deaths	2.67
All flocks (87 ewes)	4 deaths	0.92 per annum

Referring to the losses of lambs that have occurred between marking and weaning for the four lambing seasons, these have been as follows:—

Flock A has lost 2 lambs from 23 marked, *i.e.*, 2.18 per cent. per annum
Flock B has lost 5 lambs from 80 marked, *i.e.*, 1.56 per cent. per annum
Flock C has lost 6 lambs from 121 marked, *i.e.*, 1.24 per cent. per annum
Flock D has lost 0 lambs from 47 marked, *i.e.*, nil

Total .. .. 13 lambs from 271 marked is 1.2 per cent. per annum

During the immediate past two seasons, a record has been kept of the losses of lambs at birth, and between birth and marking. The numbers for each flock for both seasons have been:—

Flock A	3 lambs, *i.e.*,	16.6 per cent. annual loss
Flock B	4 lambs, *i.e.*,	7.7 per cent. annual loss
Flock C	6 lambs, *i.e.*,	8.3 per cent. annual loss
Flock D	1 lamb, *i.e.*,	3.3 per cent. annual loss
Total	14 lambs, *i.e.*,	8.1 per cent. annual loss

These losses, especially amongst the ewes, have been small, and indicate that the natural pasture is healthy for stock and suitable for wool production. When well improved by top dressing with phosphates and lime its growths are better for lamb breeding, and develop better sheep.

Summarily, the results of top dressing this natural pasture show a large increase in wool production per acre. The averages for the past four seasons show that the unmanured land has returned 8.45lbs. of wool per acre per annum; the same virgin land fertilised with superphosphate only has returned 27.76lbs. of wool (228 per cent. increase); fertilised with lime and superphosphate it has returned 28.27lbs. (234 per cent. increase), and fertilised with rock phosphates it has returned 17.75lbs. of wool (110 per cent. increase per annum) per acre per annum.

(To be continued.)

THE IMPORTANT PASTURE PLANTS OF SOUTH AUSTRALIA CONSIDERED AS TO THEIR IDENTIFICATION AND CHARACTERISTICS.

[By E. M. HUTTON, B.Ag.Sc., Field Officer.]

(*Continued from page* 344.)

C.—PLANTS, OTHER THAN GRASSES AND LEGUMES, OFTEN OF IMPORTANCE IN PASTURES.

1. EVENING PRIMROSE (*Cenothera odorata*).

This herbaceous biennial belongs to a small family of plants called the *Oenotheraceae.* In its young stages it exists as a rosette of narrow, hairless lanceolate leaves with slightly wavy margins and white midribs. Later the plants develop stiff, upright stems, which are hairy only in the upper half. The broader leaves of the stem are hairy, and half clasping. (See Fig. 43.) The conspicuous, yellow, sweet smelling flowers occur in a long leafy spike,

Fig. 43.—Evening Primrose (*Oenothera odorata*).

Fig. 44.—Rib Grass (*Plantago lanceolata*).
[*From Black's "Flora of S.A."*]

and they tend to be purplish when they fade. Evening primrose produces a large number of small brown seeds in the basal portion (ovary) of the stemlike tube beneath the flower.

It has a deep taproot system, and grows best in relatively poor sands, especially in the better districts as at Keith, Tintinara, Port Vincent, and Roseworthy. Its feeding value is relatively high, and it grows most of the year, the growth having a spring and summer incidence. In a paddock seeded down to a pasture mixture

containing Evening Primrose, it will be found after a few years that the Primrose is practically confined to the sandy rises. There is no doubt that Evening Primrose, probably with Dwalganup Early Subterranean clover, has a definite place on poor sandy soils of the cereal cultivation belt.

2. PLANTAIN or RIB GRASS (*Plantago lanceolata*).

This herbaceous perennial belongs to a small family of plants called the *Plantaginaceae*. In the early stages it can be recognised by its rosette of toothed lanceolate, dark green leaves, which are often woolly and hairy, and which are conspicuously ribbed longitudinally. Later several flower stalks bearing short spikes of small flowers are developed. (See Fig. 44.) Each flower produces two dark oblong seeds which are channelled on one face.

Rib Grass is a common constituent in the pastures of the settled districts. It does not possess a very high nutritive value, but is relatively rich in iron, and thus has medicinal properties. For this reason it is often included in English

Fig. 45.—Hog Weed (*Polygonum aviculare*).
[*From Black's "Flora of S.A."*]

Fig. 46.—Wild Geranium (*Erodium botrys*).
[*From Black's "Flora of S A."*]

pasture mixtures. A sprinkling of rib grass through a good sown pasture is therefore of benefit, rather than a disadvantage. On poor dry soils it often forms one of the main constituents of natural pastures, and its chief value here lies in the fact that it provides green picking in the hotter months for stock, because its growth is mainly confined to the spring and summer.

3. WIREWEED or HOG WEED (*Polygonum aviculare*).

This is a hairless, prostrate annual, belonging to the family *Polygonaceae*, to which belongs the Docks, Sheep Sorrel, and Prickly Jack. It has small lanceolate leaves, long stiff wiry stems, and very small pinkish flowers, each of which forms a small reddish-brown nut. (See Fig. 45.)

Although a troublesome weed, particularly on stubbles, it has a high nutritive value when young, in spite of its large amount of fibre, and is highly prized in many cereal districts for fattening sheep in early summer.

4. WILD GERANIUM or CROWFOOT (*Erodium botrys* and *Erodium moschatum*).

The former appears to be commoner in the districts receiving 22ins. rainfall and over, while the latter appears to be more frequent under 22ins. rainfall.

E. botrys often adopts a rosette habit in the young stages. It can be definitely recognised by the fact that the leaves are cut into toothed lobes halfway to the midrib. (See Fig. 46.) It has purplish flowers and the beak which is formed from the flower is very long, being 2½ins. to 4ins. in length. In *E. moschatum* the leaves are cut into definite segments to the midrib, and the pale purple flowers develop short beaks 1 to 1½ins. long. (See Fig. 47.)

At the Waite Institute, Trumble and Fraser (Bulletin No. 268 of the Department of Agriculture) found that *E. botrys* became an important constituent of topdressed natural pasture, mainly because it responded to the superphosphate

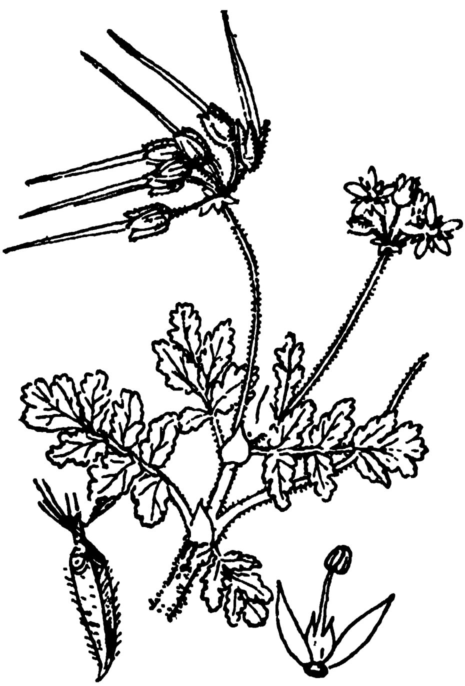

Fig. 47.—Wild Geranium (*Erodium moschatum*).
[*From Black's "Flora of S.A."*]

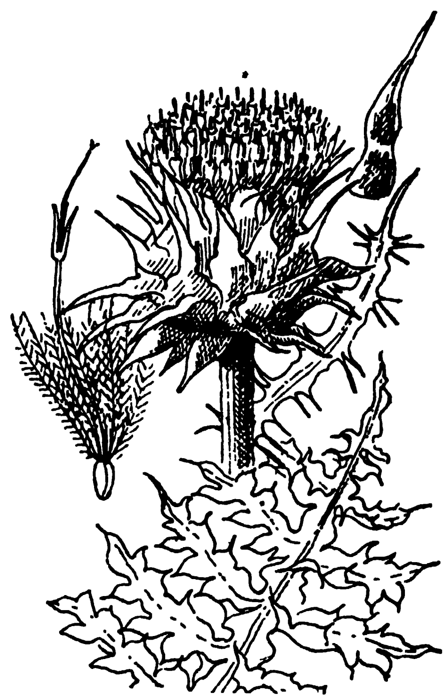

Fig. 48.—Wild Artichoke (*Cynara cardunculus*).
[*From Black's "Flora of S.A."*]

and to added nitrogen, due to the stimulation of clovers, and because grazing favours the development of plants with a rosette of leaves close to the ground. In C.S.I.R. Bulletin No. 49, it is pointed out that *E. botrys* has a high mineral content on top-dressed soil, having at the flowering stage an unusually high percentage of nitrogen and lime (each about 4 per cent.), and a very high phosphorous content (about 1 per cent.) when compared with such pasture species as Subterranean Clover and Wimmera Rye Grass. In spite of its high mineral content, its

value in pastures is limited by the fact that it produces no green feed for six months of the year, and is suitable for grazing for less than a month, being one of the first pasture annuals to mature. At maturity, about 30 per cent. of the dry weight of the plant is in the sharp inedible seed formed. As $\frac{2}{3}$ to $\frac{3}{4}$ of the plant nutrients are in this inedible seed, the plant is useless for stock at this stage.

The same remarks would apply to *E. moschatum*.

5. WILD ARTICHOKE (*Cynara cardunculus*).

This stout, erect, perennial belongs to the *Compositae,* which is practically the largest family of plants and which contains such common plants as the thistles, dandelion, chicory, stinkwort, and groundsel. The leaves are much dissected into lobes, each lobe terminating in a spine. (See Fig. 48.) The numerous small blue flowers are clustered into a large flowerhead, which is surrounded by a number of sharp, rigid, leaflike bracts at the base.

Wild Artichoke is common on waste land and along the roadsides of the better settled districts as at Clare, Morphett Vale, and Salisbury. It appears to prefer heavy to medium soils, and at least an 18in. rainfall. Its main value lies in the fact that it produces a succulent forage in the dry November to February period. It is especially relished in the younger stages, when the spines are not so well developed. Ensiling wild artichoke converts it into a useful forage by softening the objectionable spines.

A spineless artichoke (*Cynara acaule*) exists naturally in isolated patches in South Australia, as at Clare and Roseworthy. It would be of definite value in some of our districts if it were developed and seed became available.

6. SALTBUSHES, BLUE BUSHES, AND EDIBLE SHRUBS.

Very little conclusive work has been done on the grazing values of these important natural groups, because they are mainly used as pasture plants in the large tracts of very sparsely populated pastoral country receiving less than a 15in. rainfall.

The mallee is practically confined to the region between the 8in. and 20in. rainfall lines, and the saltbush flora becomes increasingly important north of the 12in. rainfall line. The best edible shrubs are mainly confined to the mallee area.

1. SALTBUSHES AND BLUE BUSHES.

These all belong to the large family *Chenopodiaceae*. Some of the commonest species of Saltbush occurring in country receiving 12in. of rainfall or more are:—Giant Saltbush, often called Oldman Saltbush (*Atriplex nummularium*—Fig. 49), Creeping or Berry Saltbush (*Atriplex semibaccatum*—Fig. 50), Angas Saltbush (*Atriplex Muelleri*), Dwarf Saltbush (*Atriplex halimoides*), Pop Saltbush (*Atriplex spongiosum*), Ruby Saltbush (*Enchylaena tomentosa*—Fig. 51), Oldman Saltbush (*Rhagodia parabolica*). In this area the important Bladder Saltbush (*Atriplex vesicarium*) is mainly replaced by the small grey *Atriplex stipitatum*. Grey Bush (*Kochia pyramidata*) is common in this region.

(1) Giant Saltbush (*Atriplex nummularium*—see Fig 49) is one of the tallest saltbushes, usually growing 6ft. to 10ft. high. It soon becomes scarce under heavy stocking, because it is readily eaten by stock. Its numerous spreading branches are clothed with fairly large, thick, succulent, almost circular, whitish leaves. The small male and female flowers are usually produced in panicles on separate plants. When not grazed this saltbush produces an abundance of seed, so that its cultivation would not be difficult.

(2) Creeping or Berry Saltbush (*Atriplex semibaccatum*—see Fig 50).—It is a perennial, with many slender, herbaceous, prostrate stems, with leaves which are greenish above and mealy-white below. In this saltbush the male and female flowers are on the same plant. When the fruits are fresh they appear as smooth, succulent bright red berries. When dry they become shrivelled and dark in colour.

At the Waite Institute Mr. Trumble experimented with Creeping Saltbush, Giant Saltbush, Dwarf Saltbush, Angas Saltbush, and Bladder Saltbush with a view to developing for the pasture areas of the cereal cultivation belt particularly, a pasture plant which will produce green succulent feed during the dry summer

Fig 49.—Old Man Salt-Bush (*Atriplex nummularum*).
[*From "Aust. Grasses and Pasture Plants," by F. Turner.*]

period. He found that Creeping Saltbush was easily the best for these conditions. At the Waite Institute this saltbush produced a dense prostrate mat of feed, which later produced abundant seed. It produced more feed than lucerne, and was able to produce over twice as much dry matter as lucerne on the same quantity of water. In C.S.I.R. Bulletin No. 49 Creeping Saltbush is shown to contain in the dry matter 15½ per cent. of soluble ash, and over 2½ per cent. nitrogen on top-dressed soil. Trumble found that this saltbush was deep rooting at the Waite Institute, and that its yield could be doubled with the application of nitrogenous manures.

Creeping Saltbush is not very well adapted to continuous or hard grazing, and it could never take the place of lucerne in those districts where the water-table is near the surface. In addition, where ensilage can be made satisfactorily, saltbushes would be of very limited value.

(3) Angas Saltbush (*Atriplex Muelleri*), Dwarf Saltbush (*Atriplex halimoides*), and Pop Saltbush are rather small insignificant saltbushes. Angas Saltbush is a low herb with thin coarsely toothed leaves, which are green above and mealy-white below. Dwarf Saltbush is a low stiff plant, with soft, thick, mealy-white leaves, and a spongy fruit with a wing near the summit.

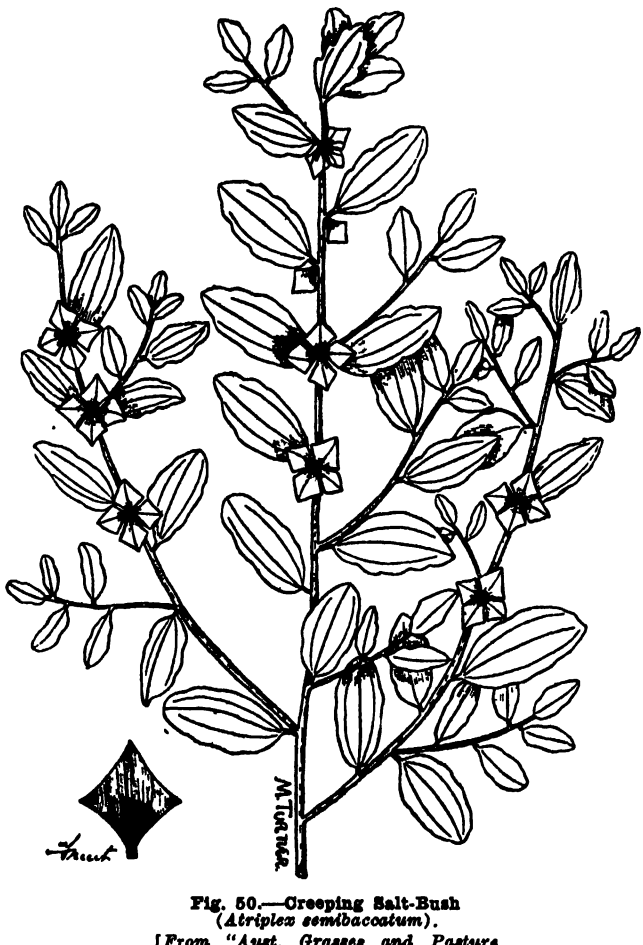

Fig. 50.—Creeping Salt-Bush (*Atriplex semibaccatum*).
[*From "Aust. Grasses and Pasture Plants," by F. Turner.*]

Pop Saltbush is very similar to Dwarf Saltbush in appearance. It can be distinguished from Dwarf Saltbush by the fact that the rounded spongy fruit is wingless.

(4) Ruby Saltbush (*Enchylaena tomentosa*—see Fig. 52).—This is a low, densely hairy shrub, with long prostrate stems, and small, slender, succulent, almost cylindrical leaves. It has small red or yellow berry-like fruits, which become black on drying. It is very common on sandy country near the sea.

(5) Oldman Saltbush (*Rhagodia parabolica*).—This is a tall-growing species which sometimes attains a height of 15ft. Cattle and sheep are particularly fond of it. It has mealy-grey leaves, which are often green on the upper surface. In this saltbush the small red globular fruit is a true berry, the seed being immersed in the pulp.

(6) Bladder Saltbush (*Atriplex vesicarium*).—This is an erect shrub about 1½ft. high, with rather thick, whitish leaves. The male and female flowers occur on different plants. The fruit is almost concealed by large, membranous, spongy appendages, on each side. This saltbush has been shown to be particularly high in minerals (23 per cent.).

(7) Grey Bush (*Kochia pyramidata*) is a many branched shrub growing about three or more feet high. The whole plant is covered with dense, soft, grey hairs. Sheep are particularly fond of its fleshy leaves. The fruit dries almost black.

The main species found within the 12in. rainfall line are Bladder Saltbush and the two Blue Bushes (*Kochia sedifolia* and *Kochia planifolia*). In this area overstocking will cause these highly palatable bushes to be eaten out, and the flora to revert to the hairless unpalatable "Bindy-eye," which possesses rather long penetrating spines on the fruit. "Bindy-eye," which is said to be a corruption of some native name, includes four species of *Bassia* which are avoided by stock because of the sharp spines on the fruit. If the land is badly eaten out, it will never regenerate and develop Bladder Saltbush again, but will remain under the useless "Bindy-eye." Relatively light and judicious stocking is thus essential for success. Rabbits (10 rabbits equivalent to one sheep) are so bad in some of the pastoral areas that they have tended to eat out the Saltbush and to cause the reversion to "Bindy-eye."

In the low rainfall areas the Saltbushes are very shallow rooted, the roots only penetrating 3in. or 4in. into the soil. The roots are deciduous, small bunches being formed when it rains. Later these roots fall off. Although the soil contains less than .01 per cent. of salt in the soil, the leaves of saltbushes contain a high percentage. As a result moisture is attracted and easily absorbed by the leaves. Dew, light showers, and air moisture (which become available through a drop in air temperature) are absorbed through the leaves and become available to the plant.

It appears that the study of Saltbushes is only of use in the lightly stocked, low rainfall pastoral areas. In the higher rainfall of the cereal belt, Saltbush could only be considered as a summer feed, and even then fodder conservation, and lucerne in some parts are much the better proposition.

2. EDIBLE SHRUBS.

Very little work has been done on the grazing value of the native shrubs. Although the best of them are confined to the 8-20in. rainfall mallee area, a number extend north beyond the 8in. rainfall line. F. Turner, in his book entitled "Australian Grasses and Pasture Plants," describes a number of the best edible shrubs in the pastoral country.

(1) Berrigan (*Eremophila longifolia*—see Fig. 52).—Other names given to this shrub are Long-leaved *Eremophila*, Native Plum Tree, Juniper Tree, Dogwood, and Emu Bush. F. Turner says: "It is a tall shrub, occasionally growing 25ft. high, with rather thick, narrow leaves, from 3in. to 5in. long, tapering into recurved points. Its drought-enduring properties are remarkable, for it grows under most adverse conditions of intense heat and aridity. Both cattle and sheep eat the leaves of this shrub with avidity, and seem to thrive on them."

It appears to grow in almost all the drier parts of Australia. Its pale-brown bark is rough and deeply fissured. It has the characteristic flower of the family *Myoporaceae*. The pink or red flower is densely hairy outside, and red spotted inside. The succulent globular fruit is blackish-purple.

(2) Butter Bush, Native Willow, Poison-berry Tree, or Apricot Tree (*Pittosporum phillyreoides*), family *Pittosporaceae*.—F. Turner says: "It is a handsome, evergreen shrub, attaining sometimes a height of from 15ft. to 25ft. It is often called 'Native Willow' on account of its pendulous smaller branchlets, which are clothed with dark-green foliage, giving it a graceful appearance, and making it a striking object amongst other vegetation. It occurs over a greater part of Australia, but principally in the arid interior, where it withstands a phenomenal amount of dry weather, without any appreciable check to its growth. Its rather narrow leaves are from 2in. to 5in. long and of a thick substance, and are much relished by cattle and sheep, which eat quantities of them in dry seasons. Even when quite young it produces a profusion of small, bell-shaped, pale-yellow flowers, which are succeeded by nearly oval fruits, containing numerous orange-coloured seeds enveloped in a sticky mass."

Fig. 51.—Ruby Salt-Bush (*Enchylaena tomentosa*). [*From Black's "Flora of S.A."*]

(3) Two members of the family *Sapindacea* are described in Turner's book.

Red Fruited Hop Bush (*Dodonaea lobulata*)—"Is a tall shrub 12ft. to 15ft. high, with thick, rigid, variously shaped leaves from 1in. to 2in. long. In many districts it is considered one of the best forage shrubs, and sheep will often stand on their hind legs to browse upon the foliage, which otherwise would be out of their reach. Its winged fruits, produced in great abundance, have a pleasant bitter flavour, and herbivora are remarkably fond of them."

Bullock Bush, Rose Bush, Rosewood, Emu Bush, or Cabbage Bush (*Heterodendron oleifolium*)—"It is found in the interior, and the leaves are from 2in. to 4in. long, and its small flowers are succeeded by seeds, each of which is partly enveloped in a red fleshy substance. In adverse seasons large quantities are cut, and both cattle and sheep feed upon the leaves with avidity and seem to do well on them."

SUMMARY AND CONCLUSION.

As R. C. Scott, Supervisor of Experimental Work, points out in his pamphlet, "Pasture Species for the Non-Irrigated Grasslands of South Australia," it is the 9 per cent. (22 million acres) of the total area of South Australia receiving greater than 15in. of rainfall with which we are mainly concerned from a pasture improvement point of view. Those regions receiving less than 15in. of rainfall (347,120 square miles) will always be a pastoral area of low carrying capacity, although there is no doubt that greater attention to its native shrubs, saltbushes, and grasses would bring about an improvement.

In the pasture areas proper (over 15in. rainfall) the main factor governing the intensity of development and the distribution of pasture species are—total annual rainfall, monthly distribution of the rainfall, mean monthly temperatures,

and the soil fertility. Trumble and Davies in the "Role of Pasture Species in Regions of Winter Rainfall and Summer Drought" have clearly shown that the South Australian climate can be classed as typically Mediterranean, that is, one having a period of summer stress followed by a period of effective winter rains. In his pamphlet, R. C. Scott further points out that even at the highest rainfall

Fig. 52.—Berrigan (*Eremophila longifolia*).
[*From "Aust. Grasses and Pasture Plants," by F. Turner.*]

centre in South Australia, Stirling West, receiving 47.08in. annual rainfall, a period of summer stress is evident, as during the six-monthly period October to May, a mean rainfall of 12.03in., or 26 per cent. of the total, is obtained, this period coinciding with the period of highest temperatures. Trumble and Davies have divided the pasture areas of the Mediterranean zone into three main areas:—

(1) The irrigated Murray swamps.

(2) The winter cereal cultivation belt receiving 15in. to 25in. per annum.

(3) The area of relatively liberal or extended precipitation receiving more than 20in. to 25in. per annum.

The pasture species which have been found by the Waite Institute and Agricultural Department to be the most suitable for the irrigated Murray swamps are:—N.Z. Certified Perennial Rye Grass, Cocksfoot, White Clover and Montgomery Red Clover as one mixture; Yorkshire Fog and Certified N.Z. White Clover as a mixture for poorly drained areas; *Phalaris tuberosa,* Kentucky Blue Grass, and Certified N.Z. White Clover as a mixture; Lucerne for mowing; Italian Rye Grass and Broad Red Clover as a temporary mixture; Prairie Grass.

The pasture species found to be the best for the cereal cultivation belt are—Lucerne; *Phalaris tuberosa* and Dwalganup Early Subterranean Clover as one mixture, and Wimmera Rye Grass and Early Subterranean Clover as another mixture in the 17in. to 22in. rainfall belt; Wimmera Rye Grass generally, especially on better class land; Burr Medic, Evening Primrose, possibly with Early Subterranean Clover, on the poor sandy soils.

In the area of liberal precipitation receiving more than 20in. to 25in. per annum, the best pasture species have been found to be Certified N.Z. Perennial Rye Grass and Late Subterranean Clover for soils of higher fertility (*e.g.*, old clover land) in areas with a favourable temperate spring, Wimmera Rye Grass and Late Subterranean Clover on second class soil (*e.g.*, bracken fern areas); *Phalaris tuberosa* and Late Subterranean Clover on both first and second class soil; Perennial Rye Grass and Strawberry Clover, or *Phalaris tuberosa* and Strawberry Clover, for the wet black lands of the South-East; Perennial Rye Grass and N.Z. Certified White Clover for rich, moist pockets of the Adelaide Hills; Strawberry Clover for marshy localities and rich swampy low-lying country; Late Subterranean Clover alone for very poor soils.

Thus it can be seen that, generally, our most useful pasture species are Perennial Rye Grass, Wimmera Rye Grass, *Phalaris tuberosa,* Lucerne, and Subterranean Clover when used in simple mixtures with low seeding rates. In special circumstances, species such as Cocksfoot, Yorkshire Fog, White Clover, and Strawberry Clover become important. Wimmera Rye Grass and *Phalaris tuberosa* appear to be the most elastic species.

The selection of the right species is only one link in the chain of pasture development. Other important links are—strain, manuring (especially superphosphate), and pasture management (especially rotational grazing, conservation of fodder as hay or ensilage, pasture renovation).

ACKNOWLEDGMENTS.

I wish to acknowledge the assistance of Mr. R. C. Scott, Supervisor of Experimental Work for reading the proofs, and for much valuable criticism and advice. In particular, I would like to thank my former lecturer, Mr. H. C. Trumble, M.Ag.Sc., Agronomist of the Waite Institute, for permission to use much of his data and his vegetative classification of grasses and clovers.

MODERN METHODS OF CHANGING THE VARIETY OF FRUIT TREES.

With a view to getting a quicker crop return and avoiding probable loss of trees through attacks by wound fungi, two new methods of re-working trees are now advocated. Both methods involve a considerable amount of time and labour, but it is claimed that the advantages of the new methods outweigh the disadvantages. Briefly, the two methods are as follows:—

PEG OR PLUG GRAFT.

The whole tree should be denuded of its laterals and "side" branches—which should be completely cut away just before commencing operations, following up the leaders to a point where an ordinary whip-tongue graft might be used. This treatment might be modified somewhat where very hot conditions prevail, sufficient lateral and spur growth being left to protect the limbs from sun scald injury.

Mr. B. Fowler (Manager of the Blackwood Orchard) giving a demonstration of re-furnishing an apple tree.

The scion, cut straight across the top, should carry two or three buds, and be about 3in. to 4in. long. It should be wedge-shaped at the base, having a short bevel not more than ½in. in length, and with a bud just where the bevel cut commences. With a ⅜in. or ¼in. chisel on which the bevel has been ground down to about double its ordinary length, or with a small sharpened screwdriver, incisions are made at right angles to the growth of the limb, with a slightly downward angle. The incisions should be on the upper sides of the limbs, 9in. to 12in. apart, and of sufficient depth to allow the wedge-shaped scions to be tapped firmly into position. No white cut surface should be showing, and the base bud should be just in contact with or slightly below the bark. It is advisable to make all incisions on lime before inserting scions. The scions should then be very carefully sealed, or rendered air-tight with either grafting wax, crude petroleum jelly, and other sealing preparation. A 50-50 combination of paraffin and crude petroleum jelly makes a very useful sealing preparation, being very plastic without being sticky.

The Bark Graft.

The scion is prepared in much the same way as for the ordinary bark-graft, with a cut surface about 1in. long on one side only, with a basal bud in such a position that subsequent growths will have room for free development. A small section is sometimes cut from one side of the wood to enable better contact to be made with the cambrium.

Various types of openings may be made in the bark, but the inverted L (˥) shape will be found most convenient. As with the peg graft, 9in. to 12in. apart is a good distance to space. For this type of grafting the bark should run freely. The downward incision should not be too long. The bark should be lifted, and the scion gently forced down between the bark and the cambium. A small tack or brad is driven through the scion to keep it in position, at the same time pinning down the raised piece of bark. A convenient form of tack is that known as the bootmaker's "tingle," or a ½in. x 20 brad will do. As with the peg graft, the whole of the cut surface of the scion should be inserted beneath the bark and carefully sealed to exclude the air. With both forms of grafting it is is wise to look over them a fortnight or so after the operation and re-seal those that require attention.

Wood for scions should be cut while the tree is dormant. They may be "heeled in" in a more or less horizontal position with the ends covered by moist sand, or be kept in cool store, standing in boxes or tins with a few inches of moist sand in the bottom.

It is generally considered that the bark graft is the most successful method, but a combination of both methods would enable the work to be started earlier, the plug graft being used for the lower and larger portion of the limbs, and bark grafts for the thinner and higher sections when the bark would run freely.

It is important that any growths rising from the old variety should be removed to prevent them becomining dominant.

THE TOBACCO INDUSTRY IN AUSTRALIA.

[*A Talk Broadcast through 5CL, Adelaide, by* R. E. COURTHOPE-GILES, *Tobacco Instructor, Department of Agriculture.*]

It is estimated that the population of South Australia expends between £750,000 and £1,000,000 annually upon tobacco manufactured in its various forms, almost the whole of which is imported from the other States of the Commonwealth or from overseas.

Although South Australia has never seriously undertaken the manufacturing side of the industry, tobacco leaf has been grown in small quantities for a number of years in various parts of the State, but principally throughout the Adelaide Hills and in the South-East, around Penola, the cured leaf sold to manufacturers in the eastern States approximating 150,000lbs. weight annually.

Growers have met with varying degrees of success, as in many cases the quality of the leaf produced has been rather inferior. The principal causes of failure have been:—The unsuitability of the soil selected for the growth of the tobacco plants; unfavourable climatic conditions; unsuitable varieties selected by growers; and general lack of experience in the growing and curing of the leaf, coupled with poor preparation for marketing.

Some months ago the Commonwealth Government voted the sum of £100,000 for the purpose of establishing the tobacco-growing industry upon a sound basis, this amount to be expended at the rate of £20,000 annually over a period of five years, and allocated as follows:—The Council for Scientific and Industrial Research, £5,000; New South Wales, Victoria and Queensland, each £3,750; South Australia, Western Australia and Tasmania, each £1,250.

The latest statistics available for the financial year 1931-1932 are interesting. The respective quantities of Australian and imported leaf used during this period were 2,349,041lbs. weight and 14,075,575lbs. weight, the total used being 16,425,000lbs., valued at £7,299,344 for manufactured tobaccos. For this same period there were over 2,000 registered growers in Australia, their production being 10,160,192lbs. weight, valued at £1,114,737.

There has always been a ready market for high-grade cigarette leaf among the Australian manufacturers, and for the bright leaf suitable for fine-cut tobacco; but the demand for the dark, heavy types of tobacco is decreasing year by year throughout the Commonwealth, which also applies to the whole world.

The object of the State authorities is to endeavour to assist the growers to produce leaf of readily saleable quality at remunerative prices. To this end, the £1,250 allotted to this State will be applied annually to the best advantage by means of practical demonstrations, instruction in the latest approved methods of tobacco culture, and by conducting a series of experiments with the assistance of established growers in the most suitable areas in the Adelaide Hills and South-Eastern districts and in the Murray irrigation areas where suitable soil is to be found, and where, by means of the overhead sprinkler system of irrigation, the disadvantage of the natural low rainfall of the areas can be overcome. The leaf produced in the Murray area, around Barmera, has hitherto been grown by the ordinary method of flooding the land, and while the smoking qualities have been of a high standard, the texture of the leaf has been very poor and brittle—entirely due to the dry condition of the atmosphere. By the use of sprays it is hoped that this difficulty will be overcome, as sprays will provide the necessary moisture in a more natural form and give the required humidity. By day all exposed portions of a tobacco plant, and particularly the leaves, are absorbing carbon dioxide from the air by means of their breathing pores, and, with water, building up a store of starch and sugar.

The establishment of a successful tobacco-growing industry would be of great value to this State. Up to the present time the smokers of South Australia have spent millions of pounds upon manufactured tobacco produced elsewhere, which moneys are almost entirely, except for the retail trade, gone beyond recall.

It is now hoped, with the financial assistance provided by the Federal Parliament, and with the co-operation of the tobacco investigations being carried out by Dr. Dickson and the Council for Scientific and Industrial Research, to produce tobaccos of high quality that will satisfy smokers, and so create a demand for local products.

Owing to the drought experienced early this year the growing crops received a severe set-back, but notwithstanding this disaster, leaf of high quality has been grown, cured, graded, and baled, and the growers are now eagerly awaiting the arrival of buyers from the eastern States, who are expected to visit us at an early date.

The harvest was very late this year, and sales are in consequence not as early as usual. Reports from the other States regarding leaf sales have been quite encouraging as far as the higher grades are concerned, and it is now realised by growers that low-grade leaf can, in the majority of cases, be avoided by improved methods, and where this is not possible the only remedy is to divert their energies into some other channel.

Leaf exhibited at the Penola Show recently was of excellent quality, some 40 entries being received in the various classes. The interest of growers was greatly stimulated by the generous action of the fertiliser manufacturers, who donated valuable prizes of special tobacco fertilisers for different grades of Lemon and Bright Mahogany leaf suitable for cigarette-making and fine-cuts.

Although the entries at the Royal Spring Show in Adelaide were not so numerous some good leaf was exhibited, and it is hoped by means of slight alterations in the schedule and, if possible, by showing tobaccos manufactured from locally-grown leaf, to make the tobacco classes of more interest to the general public next year.

The most successful growers in South Australia are located in the heaviest rainfall areas of the State—between Mount Barker and Victor Harbour and in the South-East, around Penola, where something like 26in. and over are registered.

The suitability of the soil is another all-important factor. The analysis of soils taken in the Old Belt of Carolina, one of the best tobacco-growing districts in the world, reads as follows:—70 per cent. sand, 20 per cent. silt, and 10 per cent. clay. It must be fairly deep and naturally well drained, to prevent excessive acidity, overlying a clay subsoil retentive of moisture, but not impervious. The humus content must be maintained; a high percentage of humus will not detract from the value of the soil for the production of bright flue-cured tobacco, providing that the rainfall is adequate and evenly distributed.

In these latitudes the lands require as much sun as possible, and should be laid out accordingly. In the Old Belt of Carolina referred to the temperature ranges between 50 degrees and 90 degrees in the shade.

A great deal of leaf produced here in the past has been grown on heavy soil, and although giving large yields, it has not proved remunerative owing to poor colour obtained, and the consequent low prices given by the manufacturers. On the other hand, sandy country without the very necessary subsoil being within, at the most, 2ft. from the surface has also caused a number of failures by loss of the soluble content of fertilisers and the moisture necessary to plant growth.

Throughout the Adelaide Hills area suitable tobacco soils have only been found in patches up to the present time, although it is probable that, with the further clearance of scrub that is slowly but surely proceeding in the sand country, larger areas suitable for the production of the light Virginian types of leaf will be found.

Much larger areas of this type of soil are to be found in the South-East, particularly in the ridge of hills which runs parallel with the Victorian border, and are generally of a sandy loam nature.

In the past it has been the custom here to sow the tobacco seed beds in October and carry out the field planting during December. This season an effort has been made to take more advantage of the warm summer months to assist in the ripening process, and in consequence the seed beds were sown very much earlier. The majority of growers hope to finish field planting before the middle of November. Another advantage obtained by early planting is to lessen the risk of an outbreak of Downy Mildew or Blue Mould disease, as it is generally known, for it has seldom made its appearance before the latter half of November, and then as a rule in the seed beds where conditions are most favourable to its contraction and spread by the Blue Mould parasite.

The necessary tobacco fertilisers are obtainable from the local distributors, and can be made up to suit particular requirements, and any advice required as to the amounts and methods of application can be obtained from the Agricultural Department.

The soil should be worked to a fine tilth, and all possible moisture conserved. After planting in the field on the check row system, which, with 3ft. spacing, will take approximately 4,800 plants per acre, intensive cultivation should be carried on during the period of growth.

The lower leaves coming in contact with the ground are valueless and should be removed as soon as the plants commence to make steady growth; this operation is known as "priming." When the plant is approaching maturity after being in the field for about three months, and is approaching the flowering stage, they should be topped. This will force the ripening of the leaf, and after a period of ten days it should be possible to commence the harvesting operations. The leaves ripen from the bottom upwards. They must be picked with great care to prevent bruising and discolouration, and be of uniform ripeness, if a satisfactory cure is to be obtained. This is rather a long process, and perhaps I may have an opportunity of saying something further on the subject at a future date.

SEED WHEAT FROM CROP COMPETITIONS.

In Wheat Competitions conducted in the undermentioned Districts the following Competitors exhibited crops which, in the opinion of the judge at the time of inspection, should produce grain suitable for seed purposes:—

Competition. Competitor. Address. Variety.

CENTRAL—

A. H. Wolf, Rosedale—Pine Head.

Oats.

Mr. W. C. Johnston advises that he inspected a crop of New Zealand Cape Oats on the farm of Mr. F. H. Wolf, of Rosedale, which he reports as being suitable for seed.

CONTROL METHODS USED AGAINST LOCUSTS AND GRASSHOPPERS.

[By J. DAVIDSON, D.Sc., Waite Agricultural Research Institute, University of Adelaide.]

Owing to the widespread plague of grasshoppers in South Australia during 1933-34, it has been suggested to me that a short survey of the usual control measures adopted against grasshoppers and locusts in various countries would be helpful to farmers and others.

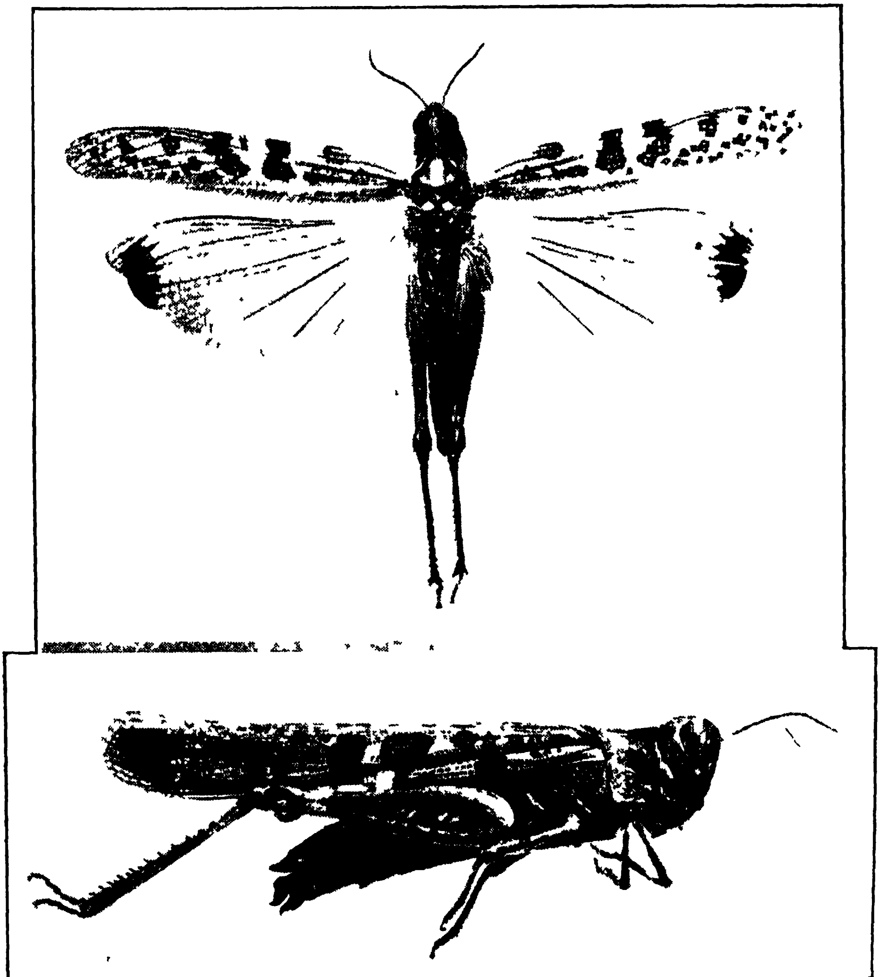

Fig. 1.—The plague grasshopper (Chortoicetes terminifera, Walk.) in South Australia, March, 1933.

The species causing the present plague is known as the "wandering grasshopper" (*Chortoicetes terminifera*). The infestation extends over South Australia, portions of the northern districts of Victoria, and western districts of New South Wales. More than one species may be involved in this widespread outbreak. The outbreaks occur at infrequent intervals of several years. The grasshoppers occur

in swarms which vary considerably in size. Compared with the locusts of the old world, the swarms are smaller and their range of migration is more restricted, so that organisation for a control campaign can be made on a more local basis.

Investigations on the ecology of the species in South Australia are being made by the Department of Entomology of the Waite Institute, in co-operation with the State Department of Agriculture. The present article gives a short general account of the chief measures which are adopted in various countries in order to reduce losses due to outbreaks of grasshoppers and locusts; many of them are applicable to the conditions existing in South Australia.

Grasshoppers and locusts belong to the same family of insects. With the former, many species live as solitary individuals, although actually they may be present in large numbers scattered over pasture areas; other species are gregarious in habits and move about in swarms. The habits of these gregarious, migrating species closely resemble those of true locusts. In general, however, locust swarms are larger and their range of migration is much more extensive.

The life-history of migrating grasshoppers and locusts is simple. The winged females lay their eggs in batches in the ground, in suitable situations, to a depth of about 2in. From these eggs, wingless hoppers hatch out; they gradually increase in size and eventually become winged males and females. The wingless hoppers and winged forms migrate in swarms, which latter vary considerably in size. The winged swarms congregate on suitable areas in order to lay eggs; these areas are known as "egg-beds," and vary in extent from a few square yards to several acres according to the size of the swarms.

The characteristic feaure of these insects is their periodic occurrence in plague numbers. In 1921, B. P. Uvarov advanced a theory to explain the reason for these periodic outbreaks; it is known as the "phase theory." According to the "phase theory" a gregarious species may be endemic in particular regions in a non-gregarious or solitary phase. Under certain environmental conditions not yet clearly understood, gregarious individuals develop in these permanent or endemic areas; these individuals multiply and form into swarms which migrate into surrounding areas. These secondary areas are only infested for temporary periods. The extent and intensity of the migration appear to be greatly influenced by weather factors. The phase theory fits well with the behaviour of certain species of locusts.

The exact locations of the permanent or endemic areas of the "wandering grasshopper" in South Australia are not known. They appear to be situated in the dry northern areas of the State, close to the line of the 10in. annual isohyet. The general direction of migration appears to be to the south. In any case, observations made during the present invasion and those recorded during previous outbreaks show that the occurrence of the insects in numbers in the agricultural areas of the State is only temporary.

It is evident that a study of the ecology of the species of grasshoppers involved in the present plague in Australia is necessary. It is also important that research should be carried out on the causes underlying their periodic occurrence in plague numbers.

1. ORGANISATION OF CONTROL MEASURES.

When a mass outbreak of grasshoppers is indicated, it is essential that control measures should be organised on a communal basis if satisfactory control is to be obtained. One important aspect of such an organisation should be the survey of infested areas so as to demarcate situations where eggs have been deposited by flying swarms. A skeleton organisation should be maintained in those agricultural areas liable to infestation, so that early control measures can be taken when an invasion is threatened. Under South Australian conditions the district council appears to be the best unit for a control organisation. It is important that occupiers of land should mark and report areas on their property where the

swarms of winged insects have laid eggs. If these "egg-beds" are defined, preparations can be made for dealing with the hoppers hatching out from them. Extensive "egg-beds" may occur on unoccupied land, surveyed roads, or State property; these should be dealt with by local councils or State organisations.

The aim in any control compaign should be the destruction of the swarms of wingless hoppers. It is generally recognised that control becomes increasingly difficult when the insects attain the winged stage. Any commonsense, practical methods may be employed in order to destroy swarms. In an organised State-wide campaign, however, certain methods are more practical than others. Of these, spraying with poison sprays, or the distribution of poison bait are methods which are widely adopted. The cost of materials and appliances used in these campaigns may be borne by the Government or by district authorities; the necessary labour can generally be arranged by owners of the land or by district councils.

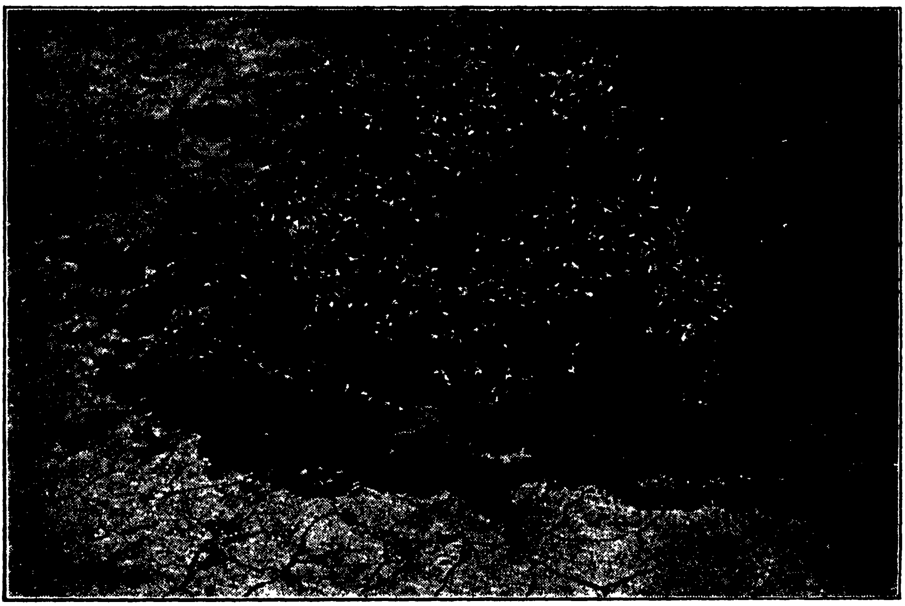

Fig. 2.—The plague grasshopper; wingless hoppers in shelter of saltbush during windy weather. North of Peterborough, S.A., Nov. 9th, 1934.

The amount of money which may be reasonably expended on control measures will depend on the value of the crops in the area threatened by invasion. It is evident that labour may be a heavy item of expenditure unless free co-operation is developed in the districts concerned.

2. SURVEY OF CONTROL MEASURES GENERALLY EMPLOYED.

Various control methods are widely practised in many countries; certain of them are suitable for use in organised campaigns, others may be employed by smaller groups of workers.

(a) Destruction of Eggs in "Egg-beds."

The insects lay their eggs in batches in the ground to a depth of about 2in.; the "egg-beds" may be a few square yards to an acre or more in extent. Where practicable, shallow ploughing or harrowing over these areas will expose the eggs to their natural enemies, such as birds, &c., and also to the influence of weather. With some species, in certain countries, the egg-pods are collected and destroyed.

(b) Destruction of Hoppers.

(1) Mechanical methods, such as destroying the hoppers by the use of rollers, chain or brush harrows, or other implements, are adopted. Their use is restricted to suitable situations and the efficiency of the method is unreliable.

(2) Hopper-catching machines are sometimes used and various types have been designed. While they may be useful in local flat situations, their application is restricted and a high degree of control is not obtained.

(3) The distribution of dry material over an area where a swarm of hoppers is present is commonly practised; the hoppers tend to shelter in the material at night and the latter can be fired at an appropriate time. The limitations of the the method are obvious. Flame-throwers of various patterns have been used, a common form being of the knapsack sprayer type; kerosene and fuel oil may be used as fuel. The method is convenient for small swarms of hoppers; owing to fuel costs it has only a restricted application.

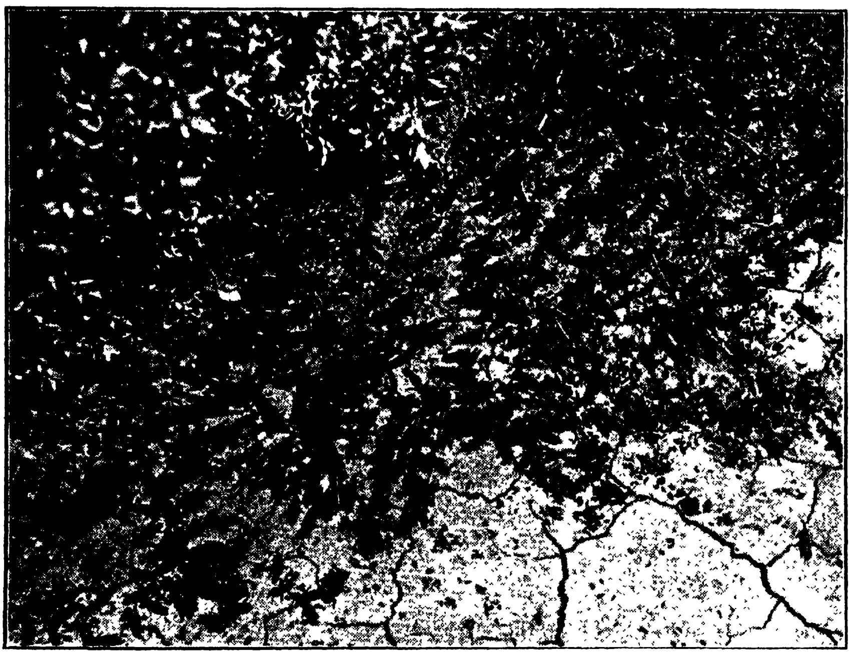

Fig. 3.—The plague grasshopper; wingless hoppers in country north of Peterborough, S.A., Nov. 9th, 1934. Note character of soil surface.

(4) The method of digging trenches to intercept swarms of advancing hoppers is widely used in certain countries. It is particularly appropriate against those species in which the hoppers advance steadily and do not readily change their direction; the hoppers may be destroyed in large numbers by this method. Following on the method evolved originally in Cyprus, barriers or screens made with suitable material are used in order to direct swarms of hoppers into pits or trenches. Sheets of smooth galvanized iron or zinc about 18in. wide have proved effective for this purpose. Barriers may be used to protect a crop from an advancing swarm of hoppers; the latter may be destroyed as they bank up against the barrier, or they may be directed into trenches. The use of the method will depend upon local conditions. Labour costs may be high where frequent changes of the position of the barriers are necessary, owing to the irregular movements of the swarm of hoppers. In suitable situations deep plough furrows will retard the advance of a swarm of hoppers into a crop.

(5) Liquid contact sprays for killing young hoppers are frequently used; they are not very effective against older hoppers. Owing to the strength of the spray required, the method is costly, and contact insecticides, such as kerosene emulsions, are harmful to vegetation. Kerosene-soap emulsions, mineral oils, and carbolic-soap emulsions may be used for spraying newly-emerged hoppers on the "egg-beds."

(6) The use of arsenical compounds as stomach poisons in the form of sprays and baits have been widely developed in many countries. Spraying has a limited application in areas where dry farming is practised; it may be used to advantage where water is readily available and the occupier of the land has adequate equipment. It is particularly useful where the herbage growth is vigorous, since baits are not suitable in such situations.

Paris green and sodium arsenite are chiefly used as the poisonous ingredients in these sprays. Molasses added to the spray enhances its attractiveness, but its presence is not essential. The following poison spray has been shown to be effective in Australia:—

Arsenite of soda	1lb.
Molasses	2lbs.
Water	16galls.

The spray should be applied on a strip of vegetation about 30ft. wide in front of the advancing swarm of hoppers. It may be also sprayed directly on to the hoppers, since it kills both by contact and as a stomach poison. It is necessary to know the arsenious oxide content of the arsenite of soda which is used; the above formula refers to an 80 per cent. arsenious oxide content.

Other forms of arsenic, such as white arsenic, are sometimes used. Stock should not have access to sprayed areas. Sprays containing soluble arsenic are liable to burn foliage. The disadvantages of the spraying method are obvious, but with heavy pasture growth good results should be obtained. In the case of a pasture crop like lucerne, it is advisable to protect the crop by spraying a barrier area around it, rather than spraying the crop itself.

(7) The poison bait method is widely used. A bait consists of an inert carrier, a poison, and an attractive substance. Bran is a useful and efficient carrier, but other convenient materials such as chaff, chopped fodder, or sawdust may be used where bran is not available. The carrier should break readily into small pieces when the bait is distributed; it must not deter the insects from feeding on the bait. Bran has many advantages as a carrier and its high efficiency offsets its cost. Experiments should be made with suitable local materials.

Arsenical poisons have given the most satisfactory and consistent results; Paris green and sodium arsenite are generally used. The soluble forms of arsenic compounds kill the insects quicker than the insoluble forms. The solubility of certain compounds in 100 parts of cold water are given below:—

White arsenic (Arsenious oxide) As_2O_3 . . .	1.2 parts.
Sodium arsenite Na_2HAsO_3	Very soluble.
Sodium arsenate $Na_3AsO_4 12H_2O$	26.7.
Calcium arsenate	Insoluble.
Lead arsenate	Insoluble.

With soluble poisons the solution of the poison is poured over the bait carrier and thoroughly mixed; with insoluble poison the bait should be mixed dry with the carrier and then made into a mash with an appropriate amount of water.

The attractive agent in the bait greatly increases its efficiency. The evidence regarding the value of the use of molasses is conflicting; where this material cannot be obtained it would appear to be justifiable to use the bait without it. In addition to being attractive to the insects, molasses assists in keeping the bait

moist for a longer period. Damp baits are more attractive than dry ones; salt is sometimes added to baits in order to assist in keeping them damp.

Other substances have been used in baits as attractants, such as crushed fruits. Further experiments are necessary on this aspect of baits.

The following fomula has proved to be an effective bait in Australia:—

Arsenite of soda	½lb.
Molasses	4lbs.
Bran	24lbs.
Water	2½galls.

The arsenite of soda is dissolved in the water and the molasses added to the solution. The mixture is sprinkled over the bran, the whole being thoroughly mixed to form a crumbly mash. The amount of arsenious oxide present in the arsenite of soda is important; the formula refers to an arsenious oxide content of 80 per cent.

The bait is scattered over an area of about 30ft. wide in front of advancing swarms of hoppers. The amount of bait required per acre will vary with the character of the area. About 10lbs. of bait (dry) should be sufficient, but in practice the amount used may be greater than this; if laid too thickly there is undue wastage of bait. The risk of poisoning stock is negligible if the poison bait is spread thinly as directed. Operators handling poison bait must observe commonsense precautions. Baits should be spread early in the morning; the hoppers become more active later in the day as the temperature increases. On cold days baiting is not so effective, since the hoppers are sluggish.

(8) The application of poison dusts, both as stomach poisons and contact poisons, has been widely developed in several countries against certain insect crop pests. During the past few years experiments have been made on the use of arsenical dusts for the control of grasshoppers and locusts. This work is in an experimental stage and would appear to have a promising future.

A dust consists of an inert carrier and the active poison. Lime, gypsum, talc, sulphur, &c., are generally used as carriers. Arsenical compounds have been chiefly used as the poison.

Appropriate dusting machines are necessary. For small swarms the knapsack or hand rotary duster may be suitable. For large areas the use of the aeroplane is gradually being developed; suitable apparatus for distributing the dust is attached to the aeroplane.

The aeroplane method appears to be particularly suitable for large areas of unoccupied or sparsely-inhabited country. It will have only a restricted application in settled areas, owing to the difficulty of efficient localisation of the dust cloud. The latter is considerably affected by weather conditions, particularly wind.

Where swarms of hoppers are scattered, as is the case of the wandering grasshopper in South Australia, the areas requiring treatment would have to be clearly defined in order to reduce wastage in materials and loss of time. In order to manoeuvre the plane over these areas considerable ground organisation would be necessary. Under these conditions the method would be costly.

Experiments have been carried out more recently with a view to testing the effect of dusting flying swarms of locusts with dusts containing sodium arsenite. It is thought that the dust will effectively kill the insects by contact.

(9) Few experiments have been made on the effect of poison gases against grasshopper swarms. The method can have only a restricted application owing to the danger to animal and plant life.

(c) Destruction of Winged Swarms.

Certain of the methods referred to in section (b) may be used. Of these, the use of poison baits and poison sprays are generally adopted. In some instances destruction of winged swarms when resting at night is possible.

EXPERIMENTAL FEEDING TESTS CONDUCTED AT PARAFIELD POULTRY STATION.

[By C. F. ANDERSON, Poultry Expert.]

A series of feeding tests are being conducted at Parafield Poultry Station with a view to ascertaining if suitable foods which are obtainable on the majority of our farms can be satisfactorily fed to poultry. The tests are each of 50 White Leghorn pullets, and commenced on April 1st, 1933.

The feeding is as follows:—

No. 1 *Test.*—Morning—Wet mash composed of 1 part crushed barley, 2 parts wholemeal (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 2 *Test.*—Dry mash composed of same proportions as No. 1 Test.
Midday—Greenfeed. Evening—Wheat.

No. 3 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts pollard (by weight), ½lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

No. 4 *Test.*—Morning—Wet mash composed of 1 part bran, 2 parts wholemeal (by weight), ½ lb. meat meal, 50 per cent. chaffed greenfeed.
Midday—1oz. wheat per bird. Night—1oz. wheat per bird.

***No.* 5 *Test.*—Morning—1½ozs. wheat per bird.**
Evening—1½ozs. wheat per bird. Greenfeed in season.

The following are the numbers of eggs laid by each pen from April 1st, 1933, to October 31st, 1934.

Definite conclusions, however, cannot be given at this juncture with regard to the various methods of feeding. It is necessary for the tests to complete the 24 months before any satisfactory opinions can be formed.

	No. Eggs Laid April 1st, 1933, to Oct. 31st, 1934.	No. Eggs Laid Month of Nov., 1934.	Total Eggs Laid April 1st, 1933, to Nov. 30th, 1934.

No. 4 test	11,556	641	12,197
No. 5 test	5,948	348	6,296

PAPERS READ AT CONFERENCES.

SOUTHERN CONFERENCE, STRATHALBYN, AUGUST 16th.

SOME REMARKS ON THE CHARACTERISTICS, CLASSIFICATION, AND MARKETING OF WOOL.

[B. S. Proctor, Mount Compass.]

From the time when wool was regularly exported from Australia it has proved to be the greatest wealth-producing industry. The drop in prices during the past three or four years has been largely responsible for the depression through which Australia is now passing. In the year 1927-28, when prices were high and wool production was almost a record, the total of £61,000,000 was received, while a contrast is provided during the 1931-32 season when the wool cheque was down to £35,073,500.

The cause of the decline in wool values was largely brought about by the manufacture of artificial wool and silk, the extensive production of these substitutes being made easy by the high prices which had been ruling for some years for genuine wool. The substitutes for wool looked attractive when made up, and were placed on the market at a very low price. However, when wool descended to a price somewhere near their own cost, these substitutes could not compete successfully against it, and when the huge stocks of wool which manufacturers had accumulated on the other side of the world gradually became exhausted the industry experienced a welcome change for the better. The promising outlook of a few months ago has latterly received a check which we all hope is momentary. The fall in prices can be attributed to political rather than to economic reasons—Germany, Italy, and Japan having greatly lessened their support owing to embargoes and restrictions on wool imports.

Characteristics of Wool.

Wool is a product of Nature, and it requires only to be separated from the grease, vegetable matter, and mineral matter which it contains to make itself at once available for manufacture. Perhaps wool's outstanding characteristic is its ability to absorb moisture and yet continue to give warmth. The possibility of contracting a chill is lessened materially when, after exertion on a hot day a sudden change of temperature occurs, for a woollen undergarment takes up the moisture and imparts a glow to the body.

Another characteristic hardly less important—especially in the manufacturing trade—is the presence of numerous saw-like edges or serrations, which are revealed throughout the length of a wool fibre when placed under a microscope. This characteristic gives wool the felting properties which no substitute textile possesses. The saw-like edges of one fibre mesh in with those of another producing a closely felted or matted appearance when manufacturing is complete. This remarkable feature which Nature has given to wool is demonstrated as soon as a fleece is shorn from the sheep's back, for a well grown, healthy fleece will hold together when roughly picked up from the board and vigorously thrown out on to the wool table. A fibre of Merino wool possesses about 1,000 to 1,200 serrations throughout each inch of its length, while a fibre of Lincoln wool shows about 500 serrations per inch. Thus it will be seen why the coarser crossbred and English-bred wools are more lustrous—they have a less broken surface from which to reflect the light. Yet another advantage which wool holds over its rivals is its ability to absorb and retain dye. Each separate fibre of wool on the sheep's back grows from the follicle situated just underneath the skin, and running from the follicle to the tip of the fibre is the hollow tube or medulla which conducts the nourishment necessary for the fibre's growth. When the

fibre is shorn from the skin the hollow tube remains open, and when the wool ultimately arrives at the dyeing process the liquid enters at the cut end. The wool fibre being of a porous and transparent nature, the dye permeates through it completely.

The elasticity of garments made from wool is an advantage distinct from any other textile; it possesses a natural curl or crimp which adds to its attractiveness and touch, and also it is much less inflammable than any of its rivals.

Wool Counts.

There are many growers of wool who do not know what the different terms such as 56's, 60's, 64's mean. These figures refer to the quality or "counts" of wool, namely, the fineness or coarseness of the wool fibre. After sorting and blending, which is followed by scouring and drying, the wool goes through the process of carding, whereby the fibres are laid parallel after their great disarrangement in the action of scouring and drying The wool comes off the carding machine in the form of a filmy mat 3ft. to 4ft. wide, and then proceeds to the combing machine, where the long and short fibres are separated. The long fibres go to form what are known as "tops," and the short fibres are termed "noils."

The tops proceed to the spinning machines to be converted into yarn, and the the terms 56's, 60's, 64's refer to the number of hanks of yarn or wool which can be spun from 1lb. of top or combed wool. A hank of wool is about 560yds. in length, so that 1lb. of 64's wool—after it has been scoured and combed, will spin 64 hanks each 560yds. in length; a 56's wool would spin 56 hanks, and so on, provided, of course, that the raw wool in the first instance is of sufficient length of staple to be termed a combing wool, *i.e.,* 2in. or more.

To differentiate in the matter of the various recognised qualities of wool is a knowledge soon obtainable by experience, and by becoming accustomed to take in the size of the wool fibre both on the wool table and on the sheep's back.

It will follow then that the greater the numeral the finer is the wool. Quality in wool is governed to a large extent by the length of the staple. Very fine quality Merino wools are short, while they lengthen as the quality becomes "stronger" or "broader," until when the crossbred wools and English-bred wools are seen their length increases up to 5in. or more.

The recognised qualities in the wool trade are as follows:—

Counts	Quality	Counts	Quality
100, 90, 80, 74, 70	Fine Merinos	58, 56	Comebacks and Fine Crossbreds
64	Medium	50, 46	Medium Crossbreds
60	Strong	44, 40, 36, 32	Coarse Crossbreds and Lincoln

In discussing wool production in Australia the saltbush or outside country produces the bulk of it. This wool is mainly of 60's, 64's, and 70's quality—all Merino wool, of course—and of such excellent type as to be responsible for Australia's reputation as a wool-producing country. It must not be forgotten, however, that this outside country could not maintain its high standard for wool production were it not able to draw periodically upon the resources of the great Merino studs which mainly exist in the inside or more settled areas. It is doubtful if we fully realise what Australia as a whole owes to the Merino stud breeders who have, by devoting their lifelong experience, utmost care, and considerable enterprise, as well as sparing no expense, succeeded in breeding

rams of a standard of excellence unsurpassed anywhere in the world. The introduction of these rams into the outside flocks is necessary to impart size to the frame, type to the body, and character to the wool of the progeny.

Wool grown in the inside country of this State—the Lower North, Hills, and Southern Districts—is of a coarser nature generally; climatic conditions having this influence upon it, and the presence of English breeds of sheep is responsible for comeback and crossbred wool. From the South-Eastern districts come the finest quality and lightest conditioned wools which look so attractive on the show floors, but natural conditions in the South-East do not lend themselves to produce the large-framed sheep of the northern areas with its robust stapled, heavy cutting fleece.

At this stage it would be well to note the effect made upon the growth of the wool fibre by a lean period in its year's growth. The sheep may be shifted on to poorer country, or after a prolonged dry spell which is now being experienced, heavy rains may fall resulting in a flush of feed causing the wool to start growing quickly. In either of the above cases a break or tender spot in the fleece occurs, which is adverse to the selling value of the wool in that it cannot go through the process of combing, as it would break under the strain. It is therefore termed a "clothing" wool, and undergoes a different process from the sound wool of combing length, *i.e.*, 2in. or over. Instances of tender wool may occur in any clip, and the grower should be most careful to see that it is kept separate from his sound wool. The State generally can expect a great deal of tender wool in this year's clip.

On the Wool Floors.

On arrival at a Port Adelaide wool store each bale is weighed, the original copy of the weight slip going to the firm's wool department in Adelaide, whilst one copy is retained at the store, and the other forwarded to the grower. Each bale is stacked with the remainder of the clip in the bulk part of the store. The stores are of two and three stories, some having an underground cellar as well. One store can accommodate up to 60,000 bales, so that the method and order has to be maintained to handle this huge quantity of wool, for throughout the wool season bales are being shipped away after each sale, while new wool is constantly arriving during about nine months of the year.

The bulk floors are laid out in the form of streets or alleyways, the bales stacked four or five high, each separate clip kept together, and each bale with its brand, description, and number visible. The location of each clip as it is stacked is recorded in an index, so that the whereabouts of any clip is easily ascertainable. All is hustle and bustle on the bulk floors at the height of the wool season, for perhaps there are four or five different wool scales weighing in wool at various points along the sides of the stores from railway trucks or motor lorries, while at the same time wool is being loaded on to trollies, to be shipped away after a sale has taken place. Men with hand trucks, on which the bales are conveyed about the stores, are moving in all directions to or from the various gangs of men who are constantly stacking the incoming wool, pulling down the stacks which are to be shipped, or sending up sample bales to the show floor, two or three stories above, for the next sale.

The area of the bulk floors and cellars of one Port Adelaide store is 15 acres, while the show floors cover 4½ acres.

All wool is sold in the order in which it arrives at the store. Prior to a sale the rough catalogue sheets are sent down from the Adelaide office, and a sample marker goes through the bulk floors and marks with chalk those bales in each different description of the various clips, which are reckoned to give a fair average indication to the buyers of each kind of wool they represent.

For classed Merino clips 3 bales are shown where the description is of from 4-9 bales, 4 bales when the number is from 10-14, 5 bales when these are 15-24, and so on up to 50 bales of one description, when about 10 bales are shown.

The sample bales are sent up to the show floor on electric elevators. The roof of the show floor is largely composed of glass to provide a good light, and the floor is planned out in streets, with the main one running the full length of the floor, and the others running at right angles to it. Each clip, as it arrives on the floor, is placed in order, running from the fleece lines down to the locks. When each bale is cut open and some wool pulled from it, an expert of the firm examines it to see that each bale is true to type and description, while he also "lots" it, giving each different description a number. From these rough sheets the catalogue is made up, and the sale is ready for inspection by the buyers, who are provided with catalogues, and proceed to make their valuations and record them alongside each lot number.

The wool buyers are sent out each season by the manufacturing firms of England, France, Belgium, Germany, America, Japan, &c., and are constantly travelling between the various capitals, as the sales are held. Brisbane and Sydney are usually worked by one section, while Melbourne, Geelong, Adelaide and Perth are worked by another.

Different sections of buyers operate on various classes and grades of wool. America, owing to a high import duty on wool, buys mostly top-grade wools, which are bulky and light, as the duty is based on weight. France buys much burry wool, as her manufacturers are able to deal with this class of wool more economically than some other countries. Germany is also a contender for top-grade wools, as is Japan, and this country was responsible some little time ago for the market for Comeback and Crossbred wools improving in price as much as 2d. and 3d. per lb.

Each buyer is kept in touch by cable with his firm of the latest trend of the wool market, London being regarded as the world's standard. He is given his "limits" from time to time, which are the highest prices to which he can bid for certain classes of wool. Arriving at a type of wool suitable to his requirements, he ascertains the "yield," the amount of cleaned scoured wool which will remain after the earth, grease, &c., has been removed. Ability to arrive at a correct estimate is, of course, a matter of experience. While arriving at a decision the buyer will test a staple here and there for soundness, for a "tender" wool is not always discernible to the eye at first glance.

Another feature to be reckoned with by the buyer of any particular wool is the "tear" or the amount of long fibres which will ultimately be combable, as compared with the short fibres, which are too short for this process. These long fibres ultimately become "tops," while the shorter fibres become "noils." The "second cuts" made during shearing are an example of "noils."

A good Merino wool will tear about 8-1, *i.e.,* there will be ultimately, after scouring and combing are done, 8lbs. of top and 1lb. of noil in each 9lbs. of wool. In manufacturing, the tops are spun into worsted or suiting cloth, etc., while the noils are woven into blankets and rugs; consequently noils are of less value than tops.

While the buyers are arriving at their values, wool experts of each firm value the wool of every separate lot on the show floor on the latest market quotations, in order to safeguard the interests of the growers whose wool they are offering.

The Wool Sales.

At the wool sale which is conducted at the Wool Exchange in Adelaide, the auctioneer has the valuations made by these experts inserted alongside each lot number in his catalogue, and if the buyers do not bid up to this valuation the lot

is passed over for the time being, and perhaps sold privately to the highest bidder after the sale, when he may pay the price asked, or, if the auctioneer deems it advisable, the lot in question may be offered at a later sale in the season. Growers sometimes take it upon themselves to put a reserve price on some of their wool. This practice is not looked upon favourably by the wool selling firms, for very few growers are in a position to form an accurate estimation of any lot of wool, and are certainly not in touch with the activities of the market whereby the correct estimation is arrived at. Many growers were reminded of this fact a few years ago, when the price of wool commenced to slump, for as some of them held to their reserve price, the market dropped lower and lower, and all hope of obtaining their original reserve, or even the price which was bid for it at auction, had vanished. The wise course to adopt is to leave the matter of disposing of the wool clip entirely to the brokers' experts, who are men with a life-long experience in the wool trade, and who possess a first-hand knowledge of the world's market.

At the wool sale the auctioneer is accompanied on the rostrum by the wool experts, and the buyers—there may be 50 of them—sit in a semi-circle before him. Bidding starts immediately each lot number is called, perhaps up to a dozen buyers shouting their bids in farthings or more at a time, some jumping to their feet or shooting out an arm in order to attract his attention, for in many cases it is the buyer who can get his bid in first who obtains the lot. The final bid is announced, along with the buyer's name, and the next lot is straightaway offered.

An auctioneer usually sells from 370 to 450 lots per hour, and is kept at high tension to note the bids from the keen buyers of all nationalities.

When the sale is over the sample bales on the show floor are sewn up and dropped below to their own clips, where the bales to be shipped are branded with the buyer's shipping mark. Before leaving the store these bales are "dumped" by hydraulic presses into half their original size, and are held by three steel bands. Most of the bales destined for export—say, from a sale of 20,000 bales—have been shipped from Port Adelaide within a week of their being sold, much of this work being done at night.

Immediately the show floor bales are dropped below, or even while the operation is in progress, new sample bales are coming up the elevators for the following sale.

Wool-selling Systems.

Star Lots.

There have been some important systems of wool selling introduced in recent years. The sample bales appearing on the show floor stand in three distinct sections. First of all are the "big lots" as they are called, *i.e.*, any lot of one brand and description containing four bales or over. These big lots are sold on sale day in the main auction room, and are bid for by a different section of buyers who purchase the "star" lots in a separate room. The star lots are of from one to three bales. The reason is obvious—the great length of time that would be taken up by selling all these star lots is minimised by having them sold at the same time as the big lots.

When the star bales come on to the show floor they are lined up along various streets according to their descriptions—fleece, pieces, bellies, and so on—no notice being taken for the time of their different ownership. Up to a certain point, however, wool from any one district is kept together.

An expert on the floor examines these star bales, and lots as many as possible together which are similar in quality and condition, and every lot of seven or more which he can arrange is classed as a "big" lot. These bales occupy one

particular portion of the floor, and are sold in the main auction room as "big" lots. They may be owned by three or four different growers, each of whom receives the same price, and is ensured of better competition than if his one or two bales had been offered in the "star" section of the floor. This system, known as "interlotting," is advantageous to grower, seller, and buyer.

The bales which cannot be matched to others to form an "interlot" are classed as "stars," and occupy a separate portion of the floor. Another important section of the catalogue is the "bag" section. Many growers have a few odd fleeces—perhaps a black fleece, two or three rams' fleeces, or some oddments —which will not go into a bale. These are mostly sent to the store in bags.

On arrival they are weighed and sent to one particular portion of the store where they are check-weighed, and the contents classed by an experienced classer into various bins according to their description, quality, and condition, &c. The wool from one bag may be classed into two or more bins, each quantity of wool being weighed and the weight entered on the weight slip. Just before each sale eventuates the wool in all the bins is baled up and sent to the show floor where it is offered just as if it constituted one big wool clip. There may be as many as 30-40 bales in any one line of fleece, lambs, or pieces, &c., and buyers are always keen to purchase a large line of wool, consequently these bales bring very good prices, and if a grower has only 10lbs. of wool in any of these lots he receives a price at the same rate as though he was offering many bales of it. This system of dealing with the bag wool is a great factor in providing the grower with a good price for his oddments.

Classification of Wool.

It is on a wool show floor that the great necessity for the systematic classification of wool is noted. All the large clips, of course, are correctly classed, and it is the owner of the flock of 500, or in some cases more sheep, who is usually at fault. Some growers roll up the fleece anyhow, with the belly and stained pieces attached, and send it thus to the wool store. If they only knew the amount of money they lost by so doing they would be astounded. Especially was this the case about 1924-27, when wool was commanding a big price. It seemed that it was selling too well for these growers, whose one idea appeared to be to get rid of the wool from the farm. Many, no doubt, would be extremely glad in these times of the money thus wasted. Of course, the brokers notice any variation in quality in the fleece lots such as Crossbred and Merino fleece being in the same bale, and they undertake to reclass clips of this nature at a charge, of course, but it seems better for the grower to have this money in his own pocket, which he can do by using a little restraint and common sense.

The bales which contain bellies, pieces, stained pieces, and locks, as well as the fleece wool, are, of course, well provided for by the buyer in estimating his value.

Woolclassing is the preparation of a clip for market in as few and as large lines as possible by keeping wool of the same monetary value and quality as far as practicable together. The reason for this is to enable a buyer to purchase a line of wool of even quality and condition suitable for his requirements.

Five points to have in mind are:—

1. Quality or fineness
2. Soundness, or strength of staple.
3. Colour.
4. Length of staple.
5. Condition, or amount of grease, vegetable matter, and earth.

Merino wools are classed chiefly on condition; Crossbred and Comeback wools on quality.

[Papers Read at Conferences.]

THE FARMER'S CLIP.

In outlining the best procedure for a farmer to adopt in getting up his clip for market, he should make as much room available as possible for the convenient handling of his wool. The less the fleeces are handled after being classed the better, and keeping them from coming into contact with earth, chaff, &c., will add to their appearance on the show floor. Partitions should be erected between which the fleeces can be stacked before baling, thereby also providing a guide for the distinction to be maintained between the various differences which may occur in the wool as it is shorn. If the baling can be done behind these partitions so much the better. A correctly made wool table is necessary for best results—battens 1in. to 1½in. wide and about 1in. apart.

When a fleece has been correctly thrown on to the table, the neck is at one end and the britch at the other. This can be accomplished easily by the picker-up if he gathers the fleece carefully from the board; first of all taking hold of either side of the britch end of the fleece and by using his feet and hands in conjunction to gather up and hold the fleece gently but firmly between his arms. Retaining hold of the britch, when the fleece is thrown, of course, ensures an even spread over the table.

SKIRTING AND ROLLING THE FLEECE.

The amount of skirting to be removed is determined by the quantity of burr and seed on the side of the fleece. In these districts, however, our wools can be termed "free" wools, so the skirting ought not to be heavy.

Starting at the neck the skirter removes any short-stapled wool on the edges of the fleece, any light, burry, or seedy portions, the "top-not," and the black-earthy, sweat-stained portions from around the legs. Fleeces must be carefully backed when necessary to remove tender heavy-conditioned wool. All this wool shows up readily, if left on the fleece, when the wool is opened for inspection, and detracts from its appearance.

In rolling the fleece, draw the britch end up to the middle of the fleece, lapping it over, throw in the neck slightly, the sides are thrown over to meet in the middle of the fleece, and it is then rolled up towards the neck end, displaying the shoulder wool, and it is then ready for classing.

On no account tie any fleeces with string or binder twine as is sometimes done for some reason.

After fleeces have been classed for some time the pieces on the floor can be picked up and sorted. If they are good, bulky pieces, remove the short, earthy edges, leaving the main portion looking more attractive and containing wool of good length staple. Class these as AA and A Pieces.

Bellies of good length staple can be treated similarly, taking care to remove pizzle stains from the wethers' bellies, which go in with the stained pieces.

The locks which accumulated about the floor and under the table can be baled up at intervals.

Lambs' wool can be classed over the wool table with advantage by covering it with hessian, two boards being effective in gathering this wool up from the shearing board.

If lambs' wool is of fair length, pick out the longest and brightest of it, marking AA lbs., while the short, heavier conditioned wool will be termed A lbs.

In suggesting possible lines for classing a farmer's clip of, say, 500 Merino sheep, the following may be of assistance:—

AA Mo.—All the brightest, lightest conditioned and longest stapled fleeces of fine quality and sound.

A Mo.—Duller and heavier conditioned than above, and shorter in staple.

Mo.—Very heavy conditioned, fatty and tender fleeces; to take a few out-types.

The farmer with a mixed flock—both Merino and Crossbred sheep—would do well to deal with his Merinos first, and bale all the wool shorn from them before commencing shearing and classing his Crossbreds. Crossbred wool is classed largely on quality. Lines for such a flock may be:—

A CBK.—Fleeces of 58's quality and finer, bright and sound.

A XB.—Fleeces bright and light and sound of 50's to 56's quality.

B XB.—Fleeces of 50's and under, bright and light.

XB.—Fleeces of 50's and under, bright and light.

As few lines as possible should be made in the clip.

In classing wool, there are usually some fleeces which do not really suit any line of the four or five which are made. They can be easily kept aside, and will probably be sufficient to form a bale with some of the oddments, such as pieces or locks. It is better to keep these fleeces apart than to force them into a line to get rid of them, and thus drag down the appearance of that line. It is better—if in doubt about whether a fleece should go into one line or another—to put into the lower class. It will tend to improve that line, but will have an opposite effect on the higher line.

The farmer should endeavour to get up his clip to the best advantage. It is more satisfaction to him, and certainly appeals more to the firms who are handling it than the untidy, slovenly bales seen sometimes in a store.

A well-pressed bale has a very neat appearance. The farmer's brand, preferably one name, should be clearly and neatly put on, both on the top and side of the bale. Underneath the brand should appear the description, and under that the number of the bale.

In consigning his wool to any firm for sale, the farmer should advise the firm of the number of bales he is consigning, the descriptions and numbers of each bale, being careful to point out any bales that perhaps contain wool of more than one description. This procedure is appreciated by the wool firms, and aids considerably in the handling of the clip while in store.

It is largely through the medium of this great industry that Australia is going to make a recovery from the financial depression through which she is now passing. It is an industry in which many millions of pounds have been invested, and when we hear of fresh substitutes for wool being experimented with in various parts of the world, and some of our chief purchasers threatening to endeavour to carry on without acquiring wool from us, we Australians ought to consider just how much we can help the industry by our own efforts. The time-worn axiom that "charity begins at home" seems to suggest itself, and we can put it into practice, with advantage to the country's income, by purchasing all our requirements, wherever the opportunity lends itself, with articles made from wool.

MURRAY LANDS EAST BRANCHES AT CALIPH ON September 20th.

FAT LAMB RAISING.

[M. J. SHANNON, Pata.]

The subject of fat lamb breeding is a far bigger one than most farmers appreciate. Instead of making it the haphazard business which is so frequently done, the farmer should give it as much attention as he does his wheat farming, and considering the profit in comparison to expenses and labour, a little consideration for his sheep, and attention during certain periods of the year, his work and outlay show a profit far beyond his most optimistic expectations.

Generally too little consideration is given to sheep on farms, and they are all too often looked upon merely as a means of keeping the farm clean for wheat farming. It is a common sight to see sheep almost starving on a fallow paddock. The owner is forcing them to do the work that he should do himself, and if he cares to take the trouble of testing the difference between sheep that have been considered and sheep that have been used as scavengers only he will find that the cost of cultivating or harrowing would have been returned to him many times over. Some time ago two local farmers bought identical rams from me. One farmer gave his sheep every consideration. He received up to 22s. 4d. for his lambs and averaged 12d. a pound for his wool. The other man made his sheep work his fallow for him. His highest price for lambs was 11s., and his wool average about 9d. The difference works out at about £46 per hundred sheep. This is without counting the higher percentage of lambs and greater yield of wool received by the first farmer. Most fallow paddocks require sheep on them at some period of the year, but use commonsense, and do not allow the sheep to suffer.

At present prices, a man with 100 ewes, giving them reasonable consideration and attention, should make approximately £100 a year clear profit. There are numbers of farmers throughout the district who are making even more. Of course, the greater number of sheep held the lower the profit per sheep, owing to the farmer's inability to give as close attention to, say, 1,000 breeding ewes as he could to, say, 200; but with a large flock he can afford to take a lower profit per head, because his aggregate return for the year is so very much larger, and he does not miss his losses as much as he would if he were understocked.

The Export Trade.

The fat lamb market is very uncertain. English livestock producers are impatient at the large amount of meat imported into England at present, and it appears as though restrictions will be placed on meat imported into the British Isles. If this happens only the best quality lamb, in all probability, will be exported from Australia.

England is the only available export market for lamb, and South Australia must send overseas only what its customers require. If their demand eases off local markets will re-act at once, to South Australia's great detriment, and it is possible that in the near future lower grade lambs will not be sent overseas. If producers of export lambs refuse to recognise this, and persist in breeding and trying to sell unsuitable lambs, they will be hit badly.

Farmers in the back country, having to contend with uncertain climatic conditions, will find it difficult to produce lambs of the desired shape and quality, because this district is not really suitable for producing certain Down types of lambs that present demands require, but it is possible, with care, to produce a grade of lamb very close to A1 quality. An enormous amount of propaganda or advertising has been done in England in respect to South Australian lambs by the Trade Commissioner (Mr. C. McCann), and also by Mr. G. A. Cooper, the latter having presented expensive trophies for lamb competitions. This has considerably assisted in creating a strong market in London for South Australian lambs, but these men can only go a certain distance, and if growers do not supply the desired quality of meat it will be useless to forward inferior lamb in the hope that it will go through. It may sell, of course, but will ultimately destroy the good name South Australian lambs are winning. These men are experts and know their business; they are at the seat of the market, and know the position and requirements better than any man in Australia.

The fat lamb market opens a very big field for expirement and profit to every farmer with sufficient land cleared and fenced to carry sheep.

[*Papers Read at Conferences.*]

About eight or nine years ago I realised the possibilities of the lamb market. I had up till then been a hundred per cent. Merino breeder, but found that over a period of years we only have approximately four months of green feed, which is insufficient to grow and fatten Merinos and get the lambs into the early markets that usually prove so profitable. My experience of English breeds was nil, having been associated solely with Merinos, but as an experiment I ordered some Dorset rams. Later I tried Suffolks and then Border Leicesters, and at present breed from Border Leicesters exclusively.

I soon found that it was possible to grow a lamb from the English breeds about four weeks quicker. That is, a lamb on good feed was ready for the Abattoirs four weeks sooner than a Merino, both being given equal conditions. It went even further. I found I could forward lambs for a longer period, because with Merinos, out of, say, 1,000 drop I would have anything up to 800 lambs left on my hands for shearing, whereas with crossbreds I would have about 200 only. This factor of a carry-over of lambs has a very definite bearing on the carrying capacity of a holding.

Border Leicester-Merino Lamb, 14½ weeks old, live weight, 110lbs. Ewe, aged 7 years.

I received a certain amount of chaffing regarding my intention of sending sucker lambs to the Abattoirs. Most people contended that the lambs would deteriorate too much during the journey, and that the experiment would be expensive; but a half truckload realised 28s. 3d. per head. That was the first load of fat sucker lambs ever sent from the Loxton district.

With our present knowledge, the doubts of years ago may seem to have been foolish, but there was no precedent to follow, and most of the sucker lambs that were being sold at the time were from sources very much nearer the market; and to take a 10 or 11-weeks-old lamb away from its mother and subject it to a long trying railway journey did—and for that matter still does—seem to be taking a risk of deterioration. If the lambs are left with the mothers until the last possible moment these lambs command a price, even after the long journey, that is very remunerative.

Actually the lambs travel exceptionally well, providing they have not been abused by over-loading and ill-treatment. No farmer need hesitate about sending lambs to the Abattoirs through fear of undue deterioration during the journey.

Many farmers make a great mistake by under-stocking. It is not uncommon to see farms carrying, say, 150 sheep when nearly double that number could be

reasonably carried. It is incorrect to have so many sheep that they are poverty-stricken all the year round, but there is a happy medium which will insure against loss of under or over-stocking.

Care of the Ewes.

Some breeders think it necessary to have their ewes mud fat for lambing, but there will be better results and less loss of ewes and lambs if the ewes are in just nice condition. This can be attributed to the fact that the lambs are not so fat when dropped, and consequently are easier for the ewes to eject. Over-fat ewes—especially young ewes—are subject to a temporary paralysis, and need constant and vigilant care and attention to save them when lambing. On the other hand, ewes in low condition—and especially when on poor or indifferent feed—will drop their lambs freely enough, but the lamb is usually very weak, and the ewes being also weak, and having to search for feed, stray off, and too often the lamb is lost and dies. Try and have the ewes in nice condition, and as soon as they lamb put them on the best feed available. Keep an untouched paddock of feed into which the lambs could be transferred as soon as possible after lambing. Do not have it too far away from the lambing paddock.

Ewes in lamb should be carefully handled. Avoid crushing them in a yard. If the yard will hold 200 sheep only put 150 in it for handling. Use the utmost care so that when they are released they do not wedge in the gateway. No effects from rough handling may be noticed at the time, but careful handling will save many lambs later.

Ewes lambing should not be unduly disturbed. Before they start to lamb ride through the paddocks frequently and get them accustomed to seeing you riding around amongst them. At first they will herd or bunch, but after a while they will take very little notice, especially if the ewes are three years old or more. You will then find when the ewes start lambing you will be able to attend them without causing any disturbance. In fact, if reasonable caution is practised they will almost ignore you.

When the ewes start lambing proper, coming in fair numbers each day, drive the flock very slowly, and without a dog, across the paddock. With a little practice and a wealth of patience practically every ewe with a lamb at foot can be drafted out. When these have been separated from the main flock gather the ewes and lambs together, and slowly take them to the better feed. This shifting of young lambs to the best feed has much to commend it, but probably only applies to a holding of 300 or more ewes. Ewes with lambs at foot are inclined to move slowly, and if mixed with dry sheep only get the second picking of the feed; the dry sheep race ahead. Ewes with twin lambs require extra care in handling, especially if one of the lambs is a bit weak, and it is better to move them by themselves. This all takes extra time and trouble, but pays in the long run. All young "hoggety" sheep and wethers should be drafted away from the ewes before the lambing starts.

Provision of Fodder.

The sowing of oats for green feed has by now proved itself to most flock-masters as a very necessary adjunct to successful lamb raising. No matter what kind of oat is sown, drill in a quantity of wheat and barley with the oats when sowing. This mixture will give half as much again to the fattening qualities of the green feed. A good dressing of superphosphate should always be given to the sowing of oats. I do not favour sowing pure barley or pure wheat for green feed. If it happens that these get away and run to head many of the sheep will founder. Oats will not cause this, and there is no risk from them at any time.

Types of Ram.

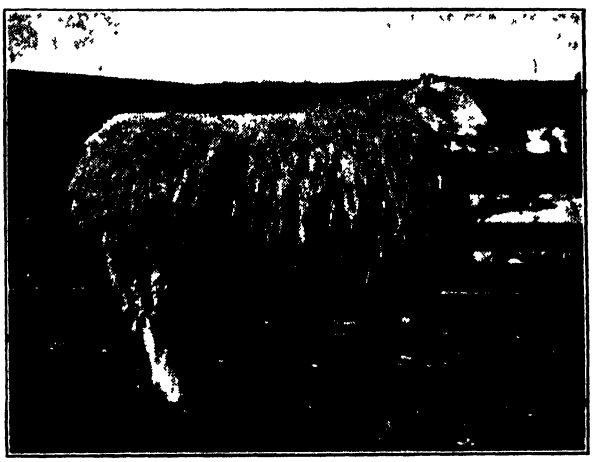
As a breeder of stud Border Leicesters, I feel I am on rather dangerous ground in commenting on any particular breed, but having tried at least three other

breeds which are fairly common throughout the district, I can only tell my experiences of the different types. If I appear to favour the Leicester remember that I have proved them to be very satisfactory.

The Dorset is a very fine sheep, strong, virile, and generally his progeny retains the Downs conformity so much talked of and admired; but his head is too big, and I have had up to 40 per cent. losses with maiden ewes during lambing, not counting many dead lambs that have had to be helped away from the ewes.

The Suffolk is an excellent ram for export lambs. The lambs have good shape and kill wonderfully well, showing a fine quantity of lean meat in comparison to fat. The lambs are quick growers, and command a good price even when the market is down, but they must be sold as lambs; if kept until full grown a large percentage will be of inferior quality. This applies more to ewes than wethers. Further, the ewes usually drop poor lambs in comparison to other British breeds.

The Shropshire ram is an excellent sheep, but is unsuitable for the outback country. He is an excellent lamb-getter, his lambs are strong, grow quickly, and are good doers; but the very woolly face makes it imperative that his lambs are



Border Leicester Ram, 13 months old, bred on the property of Mr. Shannon.

disposed of before the grass seeds are bad. This factor of having to dispose of lambs by the end of, say, September has a very big part to say in the choice of rams for fat lambs for sale. I have never used a Shropshire ram, but several breeders who have used them say that maiden ewes mated with this ram experience the same difficulty as ewes mated with the Dorset.

Many men like the Corriedale, and he is certainly a very good wool-getter, and although several have tried him in this district he has still to prove that he is suitable for the drier areas.

With the Border Leicester I have never had any trouble with lambing that could be traced to the ram. They have the smallest head of any ram. Their lambs are wonderful doers, and command a price at the sales equal to, if not better, than almost any other breed, and if they have to be kept on the farm they are exceptionally good mothers and grow to magnificent sheep. Their wool will quickly fill a bale, and often realises a price on a par with Merino. They are wonderful walkers, and can cover large areas in the search for food. If given a setback through lack of feed or some other cause they usually recuperate very quickly when conditions become normal. He has one fault, and that is he is inclined to be a shy worker, but once started makes up for lost time.

Then there are Lincolns, Polwarths, Romneys, Hampshires, Southdowns, and a host of others, each of which has its good points. In dealing with the British breeds the Merino ewe has been taken as the medium for lambs, and except for a good Comeback farmers will be well advised to stick to them.

THE MERINO.

This breed is too well-known to mention more than briefly, but the ram of this breed is definitely unsuitable for producing fat lambs for export, except in small numbers and on the very best of feed. One setback and the lamb will never properly recover from it. Every farmer has a few sheep amongst the flock that show effects of some trouble during their early life. The number may be small, because the lamb affected will in all probability not reach maturity.

So far as possible, only breed from ewes that are well sprung—ewes that have a large carrying capacity. If the ewes are small and narrow across the back there will be some risk in getting a good lambing percentage. A strong-wool ewe is always the best for utility purposes, and it pays to cull all ewes that are too fine in the wool, as they are usually the first to go when times are bad; also their lambs are not always so robust as they might be.

Always remember that it is necessary to keep the lambs improving in growth and appearance. Everything should be done to keep up the quality of the sheep. Many of the details of this paper are not of much value when seasons are exceptionally good, but if the season is average, or below, it is essential to have all the finer points right up to the mark.

LOOKING AFTER THE LAMBS.

Do not allow the lambs to get too big before tailing them. Three or four weeks I have found to be a very good age, provided that the lambs have been on good feed. I use searing irons for this purpose, and find it gives the lamb anything up to a fortnight's advance over the lamb knifed. It not only leaves the lamb with its normal amount of blood, but does away with the fear of deleterious germs. Handle the lambs carefully; they are very young, and can easily be injured for life. Do not overcrowd the yard, and try and pick the lamb up with both hands under its brisket. If you catch it by the leg keep your hand down low. If you hold the hind leg too high you are very liable to dislocate the hip joint. This also applies to grown sheep.

When castrating and tailing, sharp tools and cleanliness are absolutely essential.

When the lambs are ready for sale or export handle them very carefully. If the dogs are the least inclined to bite, muzzle them. Do not poke the sheep with sticks or anything pointed, and, most important of all, never, under any circumstances, grab a lamb or sheep by its wool. More lambs are rejected in the freezing works from effects of being grabbed by the wool than from all other causes. Farmers would be astounded if they saw the great bruises caused by the pulling of the wool. Buyers know the brands of the lambs they buy, and will only buy, so far as possible, brands which have proved to have the smallest number of rejects.

A lamb is ready for export when the live weight reaches about 85lbs. When trucking, do not overload the lorry to such an extent that when the siding is reached half the lambs are down and dirty. An inch or so of sand on the bottom of the lorry will go a long way in allowing the lambs to get a footing, and it will also absorb the liquid and droppings. Grating is the best, but few trucks have this.

Do not overload the railway truck. Each compartment holds comfortably 60 of the 85lb. lambs. If big sheep are mixed with lambs allow a little more looseness than with the same size sheep right through; also remember that under-loading is expensive. One has to pay just the same for 45 lambs as for a full 60 load. The expenses on a 60-lamb load—that is, a quarter van—run into approximately 1s. 9d. per head. This covers railage, untrucking, yard fees and commission, and the

difference in the price received at the Abattoirs to the local market is so great that last year dealers were operating at the local market and sending the lambs down to the Abattoirs and doing wonderfully well.

If there are not sufficient lambs ready to make a truckload, get in touch with your neighbours or the local agent and help fill a quarter rail van. Brand all the lambs, and the agency in Adelaide will attend to all other matters.

The argument may arise, "Does it pay to sell lambs as suckers in preference to holding them until full grown." My experience says, decidedly yes. Over all the years in which I have been sending away lambs only one year was unprofitable. It is customary to receive as much for a 10 or 12-weeks-old lamb at the Abattoirs in season as will be obtained for the same lamb 12 months later. In fact, if the lamb market is strong there will be a loss in value by holding. I saw several cases of that last year when neighbours, to make up a truckload, included some of their previous year's lambs, and received shillings a head less for them than the sucker

"The correct way to pick up a lamb." Both hands open under its brisket.

lambs. Not only that, but by selling the lambs off the mothers, and before the lambs have had time to pull the ewes down in condition, there will be a better wool clip, the ewes will do with less feed, and their longer period of dryness will ensure a better and quicker lambing next season.

By selling the lambs as suckers the flock can be increased. The lambs come during the flush period of the feed, when the carrying capacity of the farms is nearly doubled. If the full carrying capacity of the farm is, say, 500 sheep one can safely have that many ewes to lamb if the lambs are sold as suckers, whereas, if held until matured, it would not be possible to hold more than 300 ewes to lamb. This would mean a loss of at least 150 lambs, besides the extra wool from the 200 ewes, or, worked out on conservative values, about £160 a year loss. It would be far better to purchase cast for aged ewes, get two lambs from them, fatten and sell. By spreading the purchases over a year or two there would not be many to fatten and sell each year. Cast for aged ewes can usually be purchased at a reasonable price, and as they are the breeding ewes of stations that would have sold them long

before if they had not been good sheep, the inexperienced man can safely buy them and know he is not getting "a pig in a poke." No man is to be blamed for holding back some of his best ewe lambs, but do not overdo it.

If it is desired to raise lambs for quick profits it will be necessary to purchase British-breed rams. The type of ewe does not matter so much, but the big, plain-bodied, strong or medium-woolled ewe will give the better lamb, mother it better, and be easily the most profitable over a period of years.

Have the ewes properly crutched about six weeks before they are due to lamb. A big blow with the blades or two blows with the machines above the udder as well as the crutch will assist the baby lamb to find the teats readily, and perhaps avoid having ewes with inflated udders and teats through the lambs not finding its milk soon enough. It also keeps down flies.

Gestation with a ewe is 150 days, or approximately 5 months. Have the lambs come as soon as practicable, but remember that a lamb dropped on green feed will usually do twice as well as the lamb dropped on dry feed. Feeding ewes on concentrated foods before lambing has proved an excellent practice. This, of course, is really only necessary when the feed is dry or poor.

If only Merino rams are used there will be a large carry over unless the feed keeps wonderfully good and all the lambs dropped within three weeks or so. If lambing is strung out it will be very difficult to place lambs before the grass seeds come. Once the seeds come the Merinos will have to be shorn, and the demand for shorn lambs has been far below the value of the wool taken off them. Crossbreds, on the other hand, are not nearly so susceptible to seeds, and can be marketed for quite a long time after Merinos are out. Exporters do not want seed-pricked lambs, and the butchers are the only buyers of this class. Naturally this limits the market, so, if possible, get the lambs away before the seeds come.

Keep the bloom on the lambs if good prices are desired. By bloom is meant that fresh, clean appearance. A dirty, dusty, dry-looking lamb, even though it may be better under the skin, cannot compare with the lamb with the bloom still on it. Do not walk the lambs over miles of dry, dirty roads to market; it is easier and far better to lorry them, and it pays.

General Management.

Use plenty of rams. Two per cent. is low enough; 3 per cent. is better. The lambs are dropped quickly, and make a much more even line. If only a few rams are used—that is, too few for the number of ewes—a ram will waste his energy on one ewe, whereas if there is competition he will serve her and move on to where there is more excitement, and in the meantime find other ewes.

Go to some trouble, and make the farm unhealthy for foxes before lambing commences. If left until lambs are dropping, that is leaving it too late. Once the foxes start on the lambs they are hard to destroy. When a burrow is found get a gallon of carbon bi-sulphide and gas them. Carbon bi-sulphide can be purchased from any stock agent, and is an excellent means of dealing with them. Poison baits are also good.

Many of these comments may appear to the average, indifferent lamb breeder to be unnecessary, and making too much trouble and work, but the time is past when the man on the land can continue slip-shod methods, and the present economic stringency calls for brains, commonsense and ability to keep the wolves off the farm. The production of fat lambs will prove a very remunerative income, coming in during a period of the year when it is extremely useful, and the aim should be to do everything to produce those lambs as early as possible, in the best manner possible, and in the greatest numbers possible.

The greatest factor in producing quality lambs is good feed, and plenty of it. It is the key to the whole business, and without it your efforts will be in vain. Grow the feed, and success is assured.

[*Papers Read at Conferences.*]

BULK HANDLING OF WHEAT IN SOUTH AUSTRALIA.

[A. T. PENGILLY, Alawoona.]

The question of bulk handling is by no means new, as the first move was made about 26 years ago, and in a report of that date it was estimated that it would effect a saving of £60,000 to £100,000 on a 20,000,000 bushel harvest, and up to £150,000 on a 30,000,000 bushel harvest; but the report further states that Commissioners, whilst feeling that the case for bulk handling was strong, did not recommend its installation forthwith owing to the unfriendly attitude of shippers and others.

They recommended, however, that experiments should be carried out by the Government and private exporters to familiarise those interested with the advantages of the system, but no action was taken by the Government until 1914, when the Vaughan Government commissioned a Canadian firm to furnish it with a full report in reference to the construction, maintenance and operations of grain elevators, handling and shipping of grain in bulk, and this was placed before Parliament on December 17th, 1915.

In March, 1916, this firm was commissioned to prepare plans and specifiations and to supervise the construction of works as set out in the report, and in August of that year a motion was submitted to the House of Assembly seeking Parliamentary sanction to proceed with the works specified, at an estimated cost of £1,100,000; but, after a lengthy debate, the motion lapsed, and nothing was done.

The next move was made in 1922, when a local company of farmers made an unsuccessful effort to establish bulk handling in South Australia. The Commonwealth Government approved of the scheme, and passed an Act to facilitate its working; but, after various alterations and amendments, the Bill introduced in the State Parliament for the ratification of the agreement was rejected on the third reading, and consequently the company did not proceed with its scheme. No further official move seems to have taken place to establish bulk handling in this State until the question was referred to the Public Works Standing Committee on October 29th, 1931, and its first progress report, which has recently been printed, is of great interest, as it gives a wealth of information on the subject collected from various parts of the Commonwealth and other countries.

SCHEMES.

Several schemes have been inaugurated. The one in New South Wales has been operating for about 10 years, and the system employed at the Sydney terminal is that the majority of cargoes are loaded by elevators or pumped into the vessel, which means that a continuous stream of wheat is poured into the holds, and an ordinary vessel can be loaded in 24 hours, and from start to finish only two men are employed under each gantry or hatch. Throughout the New South Wales wheat belt silos are erected at various sidings, and the scheme is certainly working most efficiently, but not profitably, and unfortunately the cost of the same does not recommend itself as being suitable for installation in South Australia. The Canadian and American systems, although they appear to be satisfactory in their respective countries, do not seem to be an economic proposition for this country on account of the different conditions which exist in the three countries, for the capital cost would be far too heavy, and farmers would have to pay a charge out of all proportion to the value of his wheat in comparison with bag handling.

The only system in vogue which, with some improvements, appears to be suitable for this State is the "bin" system as used in Western Australia by the Westralian Farmers Limited. The difference between the "bin" and "silo" system is:—Silos are made of wood or concrete, are cylindrical in form, and are usually placed on a heavy foundation and carried to a considerable height above the ground. The bin, on the other hand, is simply a shed with reinforced sides and a floor laid down on ground level in the ordinary way. The Westralian Farmers Limited have installed several such bins, and the experiment is proving satisfactory, and appears to be both practical and economical. One farmer in Western Australia states that he has saved £103 by handling his crop of 12,400 bushels in bulk instead of bags, representing a saving of 2d. per bushel.

In 1932 the Public Works Standing Committee appointed a sub-committe, consisting of the Director of Agriculture (Professor A. J. Perkins), the Railways Commissioner (Mr. C. B. Anderson), and the Chairman of the Harbors Board (Mr. A. E. Farquhar) to further investigate the question of bulk handling, and the following are some of their recommendations:—1. The scheme must be entirely self-supporting. 2. The scheme shall operate over the whole of the broad gauge railway zone, with two terminals, one at Port Adelaide and one at Wallaroo. 3. That the minimum number of bushels delivered at a country siding to warrant the erection of elevator accommodation shall be 30,000 bushels.

The sub-committee further recommended that similar bins to those at present in use in Western Australia should be erected at country sidings, but at the terminal at Wallaroo it suggested the erection of a concrete turnover plant, and at Port Adelaide two alternative schemes were put forward, one consisting of an orthodox plant situated on a wharf site, and the other a concrete storage and turnover plant in Kingston railway yard, from which containers would be filled and emptied in the ship's hold by means of luffing cranes. The actual operation involved is that the

wheat after being weighed on a road weighbridge is emptied from the farmer's wagon or truck into the boot of a portable bucket elevator, from which it is delivered either direct into railway trucks or into the storage bin through an opening in the roof. The farmer unloads his own truck with the assistance of one man, who takes care of the elevator, and the wheat is similarly delivered from the sheds to the trucks, and so on. The estimated rate of loading into vessels is about 240 tons per hour at Wallaroo, and about 5,000 tons per 18-hour day at Port Adelaide.

The sub-committee was asked to devise a scheme that would be self-supporting, and in order to do this they considered it necessary that an initial charge of 3d. per bushel should be made for wheat passing through the terminal and 2½d. per bushel for bulk wheat consumed locally. The present cost of bag handling is estimated at 2½d. per bushel. The result of the scheme recommended by the sub-committee would be a net saving of £147,000 per annum to the wheat industry, which is based on all wheat being handled in bulk, and on the average harvest for the last nine years, made up as follows:—

Saving in bags at 9s. per dozen (assuming the farmer required 10 per cent. of the present bags per annum)	£174,487	
Saving in shipping freight, 270,000 tons at 2s. 6d. per ton	33,750	
		208,237
Less additional cost of bulk handling over bag handling, 15,500,000 bushels at ½d. per bushel	32,292	
Less value of bags paid for as wheat	29,062	
		61,354
Total saving per annum		£146,883
		(or 2.274d. per bushel)

An even greater saving could be expected, for at the moment there is in existence a plant for conveying wheat by suction from one container to another, and finally into the ship's hold, and which it is claimed is far more efficient and economical than the elevator system, and the danger of cracking the grain is said to be entirely eliminated. This being so, one could reasonably expect even better results than anticipated by the sub-committee.

Control and Management.

This is so vital to the success of this or any scheme that before expressing an opinion I will quote the suggestion of the sub-committee, and endorsed by the Public Works Standing Committee, *i.e.*:—

That the scheme should be controlled by a Board of three Government representatives and two private members, composed as follows:—

(*a*) Three Government representatives:—(1) the Railways; (2) the Harbors Board; (3) the Department of Agriculture.

(*b*) Two private members:—(1) a representative of the wheatgrowers; (2) a representative of the wheat merchants.

On first sight, and after the recent experience of a board of Government nominees controlling farmers, it is apparent that the suggested composition of the Board will not meet with the approval of the producers with its ratio of 4 to 1; and seeing that the whole success of the scheme depends on the co-operation of the wheatgrowers, their views must be given every consideration before any definite decision is arrived at.

Throughout the whole of the State there is strong opposition to any form of Government control of bulk handling, and the concensus of opinion is that the

scheme should be financed, operated and controlled by a co-operative company of farmers and private enterprise. There is a possibility of some such system being established.

The control of the scheme by any one firm to the exclusion of the farmers would also meet with a very cool reception; but there is one point which must not be overlooked, and that is *that a farmer only possesses an interest in silo-stored wheat so long as he retains his warrant,* and immediately he sells the ownership of the wheat passes to the buyer, who, in all fairness, is surely entitled to some voice in its control.

Displacement of labour at sidings and terminals is often advanced as an argument against bulk handling, but the displacement of labour by the introduction of machinery which assists in industry should not be taken into consideration or borne by any single industry, but should be borne by the nation, as is the case with labour displaced by machinery.

GENERAL.

Seeing the sub-committee, after an exhaustive inquiry into all systems of bulk handling and careful consideration of all evidence tendered, saw fit to express the following:—"The sub-committee is definitely of the opinion that bulk handling is warranted in South Australia," and that the finding of the Public Works Standing Committee was, "that, in the interests of the wheat producer, it is desirable to introduce a system of bulk handling of wheat into South Australia on the lines recommended by the Bulk of Handling of Wheat Sub-Committee," one has no hesitation in recommending a suitable system of bulk handling to the favourable consideration of farmers in South Australia.

CARE OF CALVES ON THE FARM.

[T. W. WILSON, Alawoona.]

Usually the first job with the young calf is to teach it discipline, and to drink from the bucket at the same time.

With this object in view, a strap should be buckled around its neck, to which a short rope can be fastened. The calf should be kept tied up until it learns to drink readily from the bucket, thus saving the time of having to chase it around the yard to feed it. New milk is given to the calf for about a fortnight; then this can be broken down with skim milk, gradually decreasing the new milk until the calf has skim milk only.

Three weeks is long enough to keep the calf tied up. It should be allowed to run around the yard at that stage, but the strap should be left on its neck for handling occasionally.

So soon as the calf shows any inclination to chew, place a box in the yard with a few handfuls of hay chaff in it and a little crushed oats or bran. The calf will soon take to this ration, and will thrive and grow faster than if fed on milk only.

Calves are better in every way if they get some skim milk until they are three months old, in addition to the chaff and corn ration, unless there is an abundance of good green feed.

It is not uncommon to see pot-bellied, unshapely yearling calves on some farms, which is mainly due to the fact that they have been turned out too early to fend for themselves. However good the blood strain of the stock may be, insufficient feed in their early lives will spoil them for stud purposes.

In the case of yearling heifers, these still need some hand-feeding in the autumn and early winter periods, when the young feed does not contain sufficient strength for the requirements of young stock. Cocky chaff will help to keep them from slipping back at this time, and give them something solid to chew at night.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on November 28th, there being present Messrs. A. J. Cooke (Chairman), J. W. Sandford, S. Shepherd, F. Coleman, Hon. A. L. McEwin, M.L.C., Professor A. J. Perkins, Dr. A. E. V. Richardson, and H. C. Pritchard (Secretary). Apologies were received from Messrs. A. J. Koch, J. B. Murdoch, and H. N. Wicks.

On behalf of the Board the Chairman extended congratulations to Mr. McEwin on his being elected a member of the Legislative Council.

The Chairman also welcomed Mr. Shepherd on his return from a trip overseas.

The Secretary reported that on October 31st Messrs. A. M. Dawkins, Professor Perkins, P. J. Baily, and A. L. McEwin met as a committee at Roseworthy College and disposed of several items subject to confirmation by the Board. The action taken in each case has been confirmed and the items are indicated below by the date (October 31st).

Branch to be Closed—Kuitpo (October 31st).—This Branch was closed, members having decided to join the Mount Compass Branch.

New Branch (October 31st).—The formation of a Woman's Branch at Boor's Plains was confirmed, the following ladies being enrolled as foundation members:—Mesdames T. Stanway, S. Chynoweth, N. Cross, M. Wright, H. Queale, T., C., and G. Rodda, M. and A. Yelland, R. Ward, A. Adams, Misses L. Stanway,* B. Chynoweth, and A. Cross.

Life Members.—Life membership of the Agricultural Bureau was conferred on Messrs. H. K. Gum, Willowie (October 31st); H. G. Johnston, Parilla; H. J. Dennis, Inman Valley; H. R. Lines and E. J. Pech, Laura; B. C. Joppich, C. H. Curnow, W. H. Jettner, and W. Stephens, Wirrabara.

New Members (October 31st).—The following names were added to the rolls of existing Branches:—Berri—N. S. Wilksch; Kybybolite Women's—Mrs. S. Shepherd; Hope Forest and Dingabledinga—Mrs. G. De Caux; Tantanoola Women's—Mrs. E. Hannan; Parilla Well—R. Johnston, A. Johnston, C. M. Houston, E. H. Thiele, A. Werner; Gladstone Women's—Mrs. Anderson; Laura Bay Women's—Mrs. A. B. Nicholls; Koolunga—R. Fuller; Tantanoola—E. D. Kiely, E. Hannan; Macclesfield —Mark Haines; McLaren Flat—T. C. Burgan; Myponga—F. Hooder, R. Skipper, G. Washington, A. McGuiness, J. Roberts; Stanley Flat—A. Turner, E. S. Dolan, W. Lee, R. J. Allen, F. Gerteau, H. Dack, W. E. Penfold; Butler—E. F. Pattenden; Kybybolite Women's—Mrs. G. Paltridge, Miss H. Watkins, Mrs. D. Chapple; Streaky Bay—A. W. J. Cook; Warcowie Women's—Mrs. L. G. Martin; Marama—E. Ware; Alma—Allan Day; Narrung—A. G. Robinson, G. Wyatt, A. Thompson, G. A. McNichol, Morchard Women's—F. Stainer; Wepowie—A. M. Ware, M. J. Gregurke; Yurgo—W. Matthew, R. Mullan; Finniss—W. Coonan; Ramco—L. C. Darling; Ramco —W. R. Stanley, G. Watkins; Cummins—J. R. Bergmann; Dudley—H. E. Wood, W. E. Dunn; Lone Gum and Monash—L. H. H. Bollenhagen; Frayville—G. N. Stott; Arthurton—C. Coleman; Kybybolite—F. R. Moore; Light's Pass—T. Gerlach; McLaren Flat—A. Sigston, J. Sigston, Jerold Shaw; Goode Women's—Mrs. C. Lutz; Penwortham—C. S. Wyman, A. W. Ahle; Murraytown—C. J. Woolford; Kyancutta—H. Walter; Lone Gum and Monash—L. Ellis; Tintinara—Stanley McIver; Barmera—A. E. Coates, W. Slaughter, C. Wyman; Wirrabara Women's—Mrs. V. Scholz, Mrs. A. Piper, Mrs. Albert Durwood; Wirrabara—P. Banfield, A. M. Mahood; Buchanan—W. Hansen; Echunga—E. Hay; Warcowie—T. J. Francis, P. J. Dee; Block E—R. Glasson; Lenswood and Forest Range—Jeff Green; Sheoak Log Women's—Miss T. Schwartz; Auburn Women's—Miss S. Shaw, Miss N. Evans; Ashbourne—O. C. Kirkham, R. C. Allingame, C. J. Pitt, K. M. Horwood, R. D. Meyer, E. W. Jarman, F. White, O. G. Watson, J. Watson; Balhannah—W. Johnson; Belalie Women's—Miss M. Neale, Mrs. Gregory, Mrs. A. Beaven, Mrs. Gilfillan, Miss Jean Cummings, Mrs. Kurtzer; Belvidere—S. J. Cheriton; Berri—E. J. Wellby; Boor's Plains Women's—Mrs. C. Yelland, Mrs. T. Petherick; Clare Women's—Mrs. W. J. Fergusson, Mrs. S. C. Lee, Mrs. H. Woods; Coonawarra—John Redman, Kenneth Allder, Norman Redman, Owen Skinner, Richard Modistach, R. Lear; Coonawarra Women's—Mrs. P. C. Stafford, Miss Mary Redman; Echunga—J. L. S. Bice; Hanson—Lyall Turner, Mrs. C. P. Turner, R. W. Humphrys, W. Woollacott, jun., A Lucas, T. E. Goodridge, H. J. Clements, F., E., and J. Goodridge; Kelly—W. Ferguson; Lameroo—V. J. Cottrell; Laura—G. Cleggett; Laura Bay Women's—Miss. G. M. Nicholls; Light's Pass—R. B. Williams; Lipson—C. E. Gale, C. M. Octoman, W. Franks; MacGillivray—J. Elsegoode, A. Waller; Marama—W. Ruskin; McLaren Flat Women's—Mrs. F. Crawford; Milang—A. A. Anderson, C. Tuckwell; Miltalie—Roy Jacobs, Arthur Bartel, Jack Bagnell, Frank Bagnell, L. J. Jackson, L. Jackson, jun., Horace Ramsey; Mount Bryan—H. L. Foot, Eric Simpson; Mount Gambier—H. L. Kennedy, J. R. Nunan, R. J. Nunan; Mundalla Women's—Miss A. Adams; Murray Bridge—L. H. Christian; Nelshaby—Henry Noll; Owen—Roy Wood, M. Galbraith; Parilla—G. E. Harding, H. K. Harding; Parilla Women's—Mrs. C. G. Smitham; Penola Women's—Miss Heather Clifford; Pinnaroo Women's—Mrs. J. Hanton, Miss Roma Hanton, Miss Dorothy Dowd, Mrs. G. Nickols, Mrs. A. Gustafson, Miss Alma Beck; Saddleworth—Alan Fraser, W. O. Coleman, Eric Wadley, J. G. Rogers, E. Lawson, Laurie Bagshaw, Keith Bagshaw; Snowtown Women's—Mrs. C. S. Lovelock; Strathalbyn—J. W. Ansell, J. S. Richardson, N. A. Palmer; Taplan Women's—Mrs. Galley; Truro—P. H. Linke; Willowie—R. I. Crisp; Wilmington Women's—Mrs. Dennis, jun., Mrs. W. Noll; Brownlow—A. J. Schmidt, B. H. Schmidt.

Present number of Branches, 341; present number of members, 7,594.

A number of items were considered in Committee.

DAIRY AND FARM PRODUCE MARKETS.

Messrs. A. W. SANDFORD & Co., LIMITED, reported on December 1st, 1934:—

BUTTER.—Weather conditions during November were very favourable for dairymen because with the cool weather and showers received the feed was kept going and milk supplies, therefore, did not fall back to any great extent. There has been a gradual decline since the peak of the season in October but has now steadied and production should maintain throughout December. The London market showed some improvement and hardening in values but afterwards was back again and at present the rates are 70s. to 71s. per cwt. Local trade was well maintained and with the decrease in dairy butter there are now greater quantities of factory prints selling locally. The following are prices ruling at present:—Choicest creamery fresh butter in bulk, 1s. 3½d. per lb., prints and delivery extra (these prices are subject to stabilization levies); store and collectors lots, 5d. to 5½d. per lb. according to quality.

CHEESE—Reports from the South-East show that record quantities are being manufactured and it is expected that the total tonnage will be 50 per cent. over the previous record. Local and Westralian trade is absorbing good quantities each week but there is a considerable surplus going forward to London as freight can be arranged. Local values are:—Large and medium, from 8d. per lb.; loaf, from 8½ per lb. at store door; delivery extra; semi-matured and matured, 8½d. to 9d. per lb., whilst London rates are ruling from 45s. to 46s. 6d. per cwt.

EGGS.—Supplies have kept up fairly well and all of sufficiently high grade have been shipped to Britain. The intermittent warm weather during November affected some consignments so that the proportions of export quality lessened but, generally speaking, the supplies were satisfactory. Rates, as is usual at this time of the year, have eased with the London export season now drawing to a close and local rates are now—Ordinary country eggs, fair average quality, 6d. per dozen net; long distance rail or shipping eggs lower; export quality, clean eggs, 1⅞ozs. and over, up to 8½d. per dozen net.

BACON.—The demand for bacon kept up satisfactorily and the turnover was met by regular supplies from the factories each week. Sales of hams have increased to a large extent and manufacturers are working at high pressure preparing the Christmas hams. Local rates are—Best quality sides, 9½d. to 9¾d. per lb.; middles, 10½d. to 11d.; heavy middles, 9d. to 9½d.; rolls, 8½d. to 9d.; hams 1s. 1d. to 1s. 2d.; cooked, 1s. 3d. to 1s. 4d. per lb.

ALMONDS.—Have been in keen demand, buyers purchasing extra stocks for the Christmas trade, and values firmed. Softshells and Brandis, 9½d. to 10d. per lb.; hardshells, 5½d. to 6d. per lb.; kernels, 1s. 11½d. to 2s. 0½d. per lb.

HONEY.—Sales continued dull throughout the month although the quality of many lines was very satisfactory. Considerable stocks are held by city wholesalers and also by apiarists. Rates at present are:—Prime quality clear extracted, 2¾d. to 3¼d. per lb.; lower grades, 1¾d. to 2¼d. per lb.

BEESWAX.—Met with strong demand and supplies were inadequate. Rates are—1s. 4d. to 1s. 4½d. per lb. according to quality.

LIVE POULTRY.—Sales are held every Tuesday, Thursday and Friday and our sale rooms are the best equipped in the State. Increasing supplies came to hand at recent sales and no doubt will improve during the next week or two. As poulterers and others are short of stocks and require large quantities for the Christmas trade keen buying was experienced at each of the auction sales held. It is expected that firmer prices will rule for prime quality stock but poorer sorts which are not suitable for table purposes do not command such keen attention. We advise consigning promptly. Crates loaned free on application. The folowing prices relised—Prime roosters, 4s. 3d. to 5s 6d.; nice conditioned cockerels, 3s. 5d. to 3s. 11d.; fair conditioned cockerels, 2s. 6d. to 3s. 3d.; chickens lower; heavy weight hens, 2s. 9d. to 3s. 4d.; medium hens, 2s. to 2s. 8d.; light hens, 1s. 5d. to 1s. 11d.; couple of pens of weedy sorts lower; prime young Muscovy drakes 5s. 3d. to 6s. 6d.; young Muscovy ducks, 3s. to 3s. 9d.; ordinary ducks, 1s. 1d. to 2s. 6d.; ducklings lower; geese, 4s. 6d. to 6s.; goslings, 3s. 6d. to 4s.; turkeys, good to prime condition, 10d. to 1s. 1d. per lb. live weight; turkeys, fair condition, 7½d. to 9½d. per lb. live weight; turkeys, poor and crooked breasted lower; pigeons, 3½d. to 4½d. each.

POTATOES.—New Season's, 12s. per cwt.

ONIONS.—New Season's, 10s. per cwt.

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the Secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the Department for fuller particulars concerning the work of this institution.

[The new Bureau subscription rate of 2s. per annum, which was recommended at the 1933 Congress, applies to all members as from August 1st, 1934, with the following exceptions:—Life Members, Branch Secretaries, and members who reside in the same house as (a) a Life Member, or (b) a Branch Secretary, or (c) a subscribing member. Subject to the foregoing exceptions, new members joining during the months of July to December will pay 2s. per annum, and those joining during the months of January to June 1s. for that period and 2s. for each succeeding year. Subscriptions must accompany the nomination forms unless the nominee is exempt.]

MEN'S BRANCHES.

SUBJECTS DISCUSSED AT BUREAU MEETINGS.

If you have no other subject in mind, here is a list from which you might choose when asked to contribute to your branch programme. The list has been compiled from published branch reports.

Agriculture.	Horticulture.	Livestock.	General.
Barley Growing.	Cincturing.	Calf Rearing.	Afforestation.
Harvest Reports.	Spraying.	Care of Farm Livestock.	Beekeeping.
Pasture Management.	Pruning.	Management of Horses.	Bird Pests.
Fallowing.	Orchard and Garden Pests.	The Brood Mare.	Blacksmithing.
Care of Machinery.	Fruit Drying.	Colt Breaking.	Book-keeping.
Control of Drift.	Drainage.	Shoeing Horses.	Preparations for Drought.
Fodder Crops.	Potatoes.	Sore Shoulders.	Ensilage.
Haymaking.	Tomato Culture.	Weaning Foals.	Labor Saving Hints.
Crop Rotation.	Vegetable Growing.	Lamb Marking.	Fencing.
Seeding Operations.	Citrus Culture.	Sheep Management.	Fodder Conservation.
Wheat Pickling.	Packing and Grading Fruit.	Wool Classing.	Vermin Destruction.
Wheat Diseases.	Budding and Grafting.	Shearing.	Care of Hides and Skins.
Wheat Varieties for the District.	Orchard Cultivation.	Sheep Dipping.	Farm Insurance.
Seed Wheat.	Rack Building.	Fat Lambs.	Tank Building.
Value of the Oat Crop.	Fruit Preserving.	Handfeeding Sheep.	Shed Construction.
Wheats for Milling.	Irrigation.	Poultry.	Farm Conveniences.
Peas.	Seepage.	Shelter for Livestock.	Concrete on the Farm.
Wheat *v.* Sheep.	Care of Orchard Equipment.	Management of the Dairy Cow.	Dam Sinking.
Wheat Varieties for Hay.	Farm Garden.	Care of the Breeding Ewe.	Scrub Farm Operations.
Crop Competitions.	Diseases of the Vine.	Pigbreeding and Management.	Farm Sidelines.
Harvest Operations.	Manures for the Orchard.	Ailments and Diseases of Farm Stock.	Bacon Curing.
Value of Agricultural Experiments.	Fruit Tree Diseases.	Sheep *v.* Wheat.	Value of Native Birds.
Cultivation.	Planting the Orchard.	Rearing Turkeys.	Noxious Weeds.
Fertilisers and Manures.	Frost Prevention.	Horse Breeding.	The Agricultural Bureau.
Cultivator *v.* Plough for Fallowing.	Fumigation for Scale Insects.	Herd Testing.	Handling Dairy Produce.
Tobacco Culture		Rams for Farm Flocks.	Farm Buildings.
Meadow Hay.			Layout of the Farm.
Review of the Past Season.			Firefighting.
			Lowering Costs of Production.
			Farm Records.
			Subdivision of the Farm.

Because of the demand for space and the large number of Bureau Reports on hand, we have been reluctantly compelled to include many papers read at Bureau meetings in "Other Reports Received."—Editor.

SOUTH-EASTERN DISTRICT.

Other Reports Received.

Branch.	Date of Meeting.	Attendance.	Subject.	Secretary.

FORTY-FIFTH ANNUAL CONGRESS.

WOMEN'S BRANCHES.

THE USES OF DRIED FRUIT.

GREATER CONSUMPTION WILL HELP AUSTRALIAN PRODUCERS.

[Mrs. E. Allder, Coonawarra.]

The dietary value of dried fruit has been established as the result of years of scientific research. It has been proved that currants, sultanas, and raisins are the natural sources of vitamins and mineral salts. They are particularly rich in vitamin B, on which depends nerve health, and supply essential iron to the blood of old and young alike. Dried fruits can be combined well with other food substances, such as bread and suet, and in this way their nutritive value is increased. They also serve as an excellent source of fuel substance, to supply energy for hard work. This is the result of the large amount of sugar which they contain.

It has been found that in currants, sultanas and raisins fruit sugar is associated with the presence of mineral salts, which consist of potash and lime, which play an important part in preventing acid conditions in the tissues of the body. It is necessary that a generous supply of mineral salts should be obtained to counteract the effect of the acid-producing foods, which are consumed in large quantities.

Dietary studies show that because of a lack of knowledge of the nutritive value of foods whole families are often underfed; they can over-eat and still suffer from malnutrition. On the other hand, with proper food, healthy bodies can be built and supplied with all the energy required for mental and physical work. The value of fruit as an every day, all the year round article of diet for all ages and all classes has been demonstrated over and over again. The medical faculty throughout the world preaches this truth, too often to deaf ears, although in theory at least the usefulness of fruit in keeping the blood pure and the skin healthy is generally admitted.

The nourishing and sustaining power of fruit—especially, dried fruit, though less widely known—is now established beyond dispute by the most careful and repeated analysis, as well as the personal experience of many. A well-known medical man, writing on dietary, says:—"The juices of fruits, as of grapes, apricots, peaches, pears, nectarines, oranges, &c., have a most benign and purifying influence on the system." On the Continent people go to the vineyards in autumn and take the grape cure; they live for a few weeks entirely on bread and grapes, eating, say, half a pound of bread and several pounds of grapes a day, and are thereby so purified and invigorated that they can return with restored health to business, pleasure, and the luxuries and indulgences which are sure to bring disease.

Unfortunately the methods of preparing dried fruits for the table are but little known, and the abundance of cheap wholesome fruit thus brought within the reach of all, and available throughout the year, has in consequence hardly begun to be realised by those whose needs it is so well calculated to supply. In order to stimulate the consumption of these fruits I have decided to give a few simple recipes for preparation in a profitable but cheap form. Apart from the delicate and rich flavour of dried fruit jam, the housewife will recognise the very great convenience of being able to fill her shelves with home-made jam at any season of the year. For instance, she will find it an advantage to choose cool weather, or a time when the sugar is more plentiful. With all fruit care should be taken to avoid over-cooking, which causes the flesh to leave the fibre. The fruit should be served firm, and not mushy, the aim being to restore it to the original appearance and flavour of fresh fruit.

To prove the economical side of dried fruit, when you buy 1lb. of dried apricots, peaches or nectarines, that would be equal to 6lbs. of ripe fruit with only the moisture and stones removed.

All the health-giving properties of the fruit—vitamins, fruit sugar, and laxative juices—are retained, and soaking in water only is necessary to restore the fruit to its original size, colour and flavour. Not only is the fruit handy to have in the house for jam-making, but it is a great stand-by for pies, puddings, &c., for hot or cold days. One can always make a meal if there is a little dried fruit on hand. In the country, where one may live miles from a shop, dried fruit is absolutely necessary.

LUNCHES FOR CHILDREN.

Mothers are puzzled at times to know what to prepare as a lunch for the children. The following makes a nice, tasty, as well as nourishing tart:—

Australian Fruit Tart.

1 teacup dried apricots.
1 teacup dried prunes.
1 teacup raisins.

Australian Fruit Tart—continued.

1 level teacup sugar.
2 tablespoons chopped citron peel.
Juice of a small orange.
½ teaspoon grated nutmeg.
½ teaspoon ground cinnamon.
¼ teaspoon ground cloves.
½ teacup chopped almonds and walnuts.

Short pastry.—Line a tart plate with short pastry. Pour boiling water over the apricots and prunes; drain, and cover with cold water, and stand 3 hours. Remove stones from prunes, and cook with the apricots in the water in which they were soaked until the water is nearly cooked away. Cool, and add the other ingredients. Place on the pastry in the plate, cover with pastry, glaze, and bake 40 minutes.

Children also appreciate the following:—Mix equal parts of raisins, sultanas and currants, put through mincer, add a squeeze of lemon juice (a few nuts mixed is a great improvement); spread on bread and butter, or between home-made biscuits. Almost any fruit done this way is nice.

For a hot day a few prepared apricots placed in a 1lb. screw-top jam jar and a jelly made and poured over makes a very tempting lunch when there is one in the family who needs a little extra care and attention.

Apricot Jam

2lbs. dried apricots (best).
5lbs. sugar.
2 quarts water.

Soak apricots overnight; drain off water; add sugar to water, and boil. Put in the apricots, and boil until the whole jellies (about 20 or 30 minutes). A few blanched almonds are an improvement.

Apricot Butter, for Sponges, Fillings, Etc.

Take ¼lb. dried apricots (soaked); stew in a little water until tender, and pass through a sieve. When cold, add 1lb. sugar, ¼lb. butter, 4 well-beaten eggs, juice and rind of 1 lemon. Mix all together; put into a jar in a saucepan of hot water, bringing water to the boil. Stir one way until the consistency of thick cream.

Boiled Apricot Pudding.

Make a good suet crust, line a basin, and lay in ½lb. soaked apricots in layers, with sugar. Add a little of the juice, cover with paste, and boil 2 hours. Serve with custard or cream.

Prune Confection.

½lb. prunes.
½lb. icing sugar.
1 white of egg.
Grated nuts.

Soak prunes over-night; stone and cook carefully until tender; lift from syrup on to a dish to drain. Whisk white of egg until stiff, beat in icing sugar gradually until the mixture is like snow. Coat each prune. Cook in a cool oven until a pale biscuit colour. Place on a glass dish, and dust with grated nuts.

To Prepare Dried Fruit for the Table Without Cooking.

Place peaches in dish; sprinkle over 1 teaspoon bi-carbonate of soda, and pour sufficient boiling water over to cover. Allow to stand 1 hour. Pour off water and cover with fresh cold water and stand over-night. Skins will now come off easily. Lift fruit from water, and make syrup; use 4ozs. sugar to ¾ pint water, and use ¾ pint of syrup to every pound of fruit. Apricots and nectarines are prepared the same way as peaches, but it is not necessary to remove skins.

These are a few very simple ways of using the fruit, which I hope will be a help to those who should use dried fruits more extensively.

Miss E. Campbell, Dip. Dom. Econ., Inspector of Domestic Arts, Education Department, delivered an address, "Food Values."

AFTERNOON SESSION.

THE MEDICINE CHEST ON THE FARM

[MRS. F. G. HICKS, Clare.]

In every home, particularly those in the country usually miles from a doctor or chemist, a medicine chest should be regarded as a necessity. Many lives are no doubt saved and serious illnesses averted when there is at hand the correct drug or medicine to at least ease the patient until medical aid can be obtained.

The chest, of course, must be kept out of the reach of children, and if a special cabinet is provided for medicine, &c., that can be locked so much the better. However, nowadays, when we all study the most rigid economy, a special cupboard is out of the question; most people of necessity have a certain shelf or portion of a cabinet reserved for the storage of remedies.

As an outline I give a list of drugs that should find a place in every home. These may, of course, and generally are, added to; each housewife usually has some particular home remedy of her own. These drugs mentioned are not by any means expensive, and on occasions prove to be worth their weight in gold:—

Lysol.—Antiseptic and germicide, useful for washing all kinds of wounds, and as a lotion for skin troubles. Strength used should be 1 to 2 teaspoons in 1 pint of hot water.

Iodine.—Apply to all cuts and bruises, will also cure warts if painted on daily before the warts grow very large.

Camphorated Oil.—As a liniment for children.

Methylated Spirits.—An effective compress, will also cure septic fingernails. Keep a jar handy, and constantly dip the fingertips in it.

Chlorodyne.—Gives relief in cases of dystentery, colic, and stomach pains. Dose—2 to 8 drops in water every 3 hours.

Picric Acid, Carron Oil.—Both remedies for burns. Pour freely on lint or cotton wool, and apply to the affected area, bandaging firmly in place.

Kerosene.—Applied immediately to a burn or scald will relieve pain and prevent blistering.

Boracic Acid.—A healing agent used in water to bathe sores and wounds or applied dry.

Boracic Ointment is also good.

Olive Oil, Castor Oil, Glycerine, and Epsom Salts should also be included in every medicine chest.

I always keep a jar of *Antiphlogistine* on hand, and on several occasions it has proved invaluable. As an illustration I will quote an incident of a little child who was ill with what proved to be pneumonia, and some 10 miles from the doctor. As there was no telephone near and it was a cold, wintry day my jar of antiphlogistine was borrowed, and a poultice applied to the little sufferer. The result was that when the doctor was obtained the patient was on the mend. Nevertheless, in a case where pneumonia is feared I do not advise anyone to depend on home treatment as it is without dispute a time to call medical assistance. I have mentioned this to emphasise the advisability of having remedies on hand. They may be idle for years, but an occasion inevitably arrives when it is not convenient to journey miles for medicine.

I consider that each medicine chest should also contain a flask of brandy. In cases of fainting, collapse, and sunstroke it is invaluable, also in cases of accident, given neat or diluted with warm water. It will usually settle one's stomach in a severe bout of seasickness.

Home Remedies.

Boracic Ointment.—Eight parts vaseline, boracic acid 1 part. Mix thoroughly together.

A Good Liniment.—One part turpentine, 1 part eucalyptus oil, 2 parts camphorated oil.

Camphorated Oil.—One small cake of camphor crushed and added to a small bottle of olive oil. Shake well.

Embrocation for sprains, backache, lumbago, &c., can be made by mixing in a bottle equal parts of vinegar and turpentine and the white of an egg. Shake well before using.

Croup.—A quick and well-known remedy is made by mixing 1 dessertspoon of methylated spirits, 2 dessertspoons vinegar, and 3 of water. Dip a strip of flannel in this liquid and wrap around throat, covering with a dry strip. Will give instant relief.

A teaspoon of vinegar will usually give relief in the most violent attack of hiccoughs.

Glycerine added to a hot lemon drink in which is dissolved 2 or 3 aspirins gives great relief to a cold on the chest and to a sore throat.

A good gargle is made as follows:—2 tablespoons each of glycerine and tannin and peroxide of hydrogen, water 8ozs. Mix and use with equal parts of water three times a day.

It is well to try and avoid an accumulation of half-filled medicine bottles. When a mixture is discontinued throw it away. I refer to any individual prescriptions that one may have made up at different times. Keep a few clean empty bottles and small jars (vaseline jars, &c.) handy. They are useful for containing home-dispensed medicines.

Bandages.

I would also advise that a small cardboard box be kept in the medicine chest. This might contain bandages, finger-stalls, a small roll of cotton wool, sticking plaster, and lint. I never burn an old ragged handkerchief, but iron and put it away with the bandages. If ever so small it will make an effective soft pad to place over a wound before bandaging. Any clean white rags can be torn into strips and rolled into bandages of all widths and lengths. It is a convenience when some member of the family comes in with a cut finger or a gashed limb, to be able to place your hand on just the right sized bandage.

A pair of forceps and a small sharp pair of scissors should be included, as well as a clinical thermometer.

In conclusion, I would mention these few rules regarding the medicine chest. Keep all remedies together in a special drawer or cabinet in a handy place. Keep everything clean and neat. Label all bottles. *Keep poison in a different place to medicine as bottles are alike and mistakes do occur.*

When in doubt, do not experiment with home treatment. Unless you are sure of the nature of the ailment, a doctor should be consulted without delay.

HOME NURSING OF INFECTIOUS DISEASES.

[Mrs. S. L. Bailey, Belalie.]

The word "infection" is applied to the vehicle by which a disease is transmitted from one person to another by the air, and with or without actual contact.

Scarlet fever or scarlatina, mumps, measles, whooping-cough, and influenza, are infectious, and make up that class of disorders known as "catching." These

diseases are very often spread by children returning to school after an attack before they are quite free from infection. Parents should remember that it is only fair to other children that special care should be taken in this matter.

General Principles of Nursing.

The patient should be isolated in a room farthest removed from the rest of the family. The room should be first cleared of all curtains, carpets, and unnecessary furnitue, and then provided with a basin in which is a carbolic acid solution (1 teaspoon carbolic acid to 1 pint of water) provided for expectoration, a large bucket or tub containing carbolic acid solution (4ozs. of carbolic acid to every gallon of water) for soiled bed linen. This must never be taken dry from the room. Handkerchiefs should not be used, but pieces of old linen, which must be immediately burned, as the secretions from the nose and throat are particularly infectious. All cups, glasses, dishes, &c., must be boiled once a day.

In all cases the patient must be given complete rest, plenty of fluids, plenty of fresh air, and the bowels kept well open.

Scarlet Fever or Scarlatina.

Many people confuse these two names, and imagine scarlatina to be a milder form of scarlet fever. This is not so. Scarlatina is the latin name for scarlet fever. This is an acute infectious disease, attended by a scarlet rash upon the body, sore throat, and often swollen glands. The patient is put to bed in a well-ventilated room. He must be given frequent gargles (two hourly), and if the throat is very painful, hot foments every four hours or an antiphlogistine plaster applied around the neck. Plenty of fluids (chiefly water) must be given as kidney trouble is often a complication. The isolation period is six weeks, and during the last week a daily bath containing lysol or carbolic acid must be given.

Measles.

An acute disease. The patient appears to have a heavy cold, and whitish spots show inside the mouth. Give a hot bath, then put patient to bed. Give a purge, avoid draughts, place the bed so that the patient has his back to the light, and keep the blinds down. Give plenty of fluids until temperature is normal; then light, nourishing diet. Pay particular attention to the eyes. They must be swabbed with boric acid solution (1 teaspoon boracic to 1 pint warm water) twice daily. Great care must be taken that the patient does not take a chill, as pneumonia is likely to occur.

Whooping-cough.

This is a common infectious disease of childhood. In all cases it is best for the child to be kept in the house as soon as the malady has declared itself. In a very mild case it need not be kept in bed, but it should be in a room of warm and even temperature. Other children must be kept away. As vomiting frequently occurs after a bout of coughing, the child must be fed after each spasm.

There is very little that can be done for this most distressing complaint. It is advisable to call the doctor, as excellent results in shortening the duration and diminishing the severity of the attacks have been obtained by the injection of vaccine.

Mumps.

This is an infectious disease accompanied by the swelling of the salivary gland in front of and below the ear. If the pain is severe hot foments should be applied two-hourly, or an antiphlogistine plaster applied. Afterwards keep warm with a piece of flannel. The bowels must be kept open, and light, nourishing diet given.

INFLUENZA.

This disease has occurred in various countries at different times, and has a vast number of names. We are told that it first received its name "influenza" because it was attributed to the influence of the stars.

Treatment.—The first essentials are rest and warmth. This means bed, of course. There is no such thing as "braving it out" or "working it off," and if the patient attempts to do so the case is very much prolonged. Give a purge at the onset, and 1 dram of ammoniated quinine. Then 10 grains aspirin four-hourly is a help both in relieving the aching and reducing the temperature. Plenty of fluids, and light diet when the temperature is normal.

CHICKEN POX.

This is an infectious but harmless disease of childhood, attended by slight constitutional disturbance as a rule, and after running its course for a few days usually ends in complete recovery. Little red spots appear, and then within 24 hours each spot has become a blister surrounded by a red area. The child should be put to bed when the spots appear, and kept there for a few days. He must be prevented from scratching the spots by fingerless gloves. Plenty of fluids must be given. Then a simple, plain diet of milk and farinaceous foods. He must not be allowed to mix with other children until the scales have fallen off.

Here is a chart that might be useful to parents showing how soon after an attack of infectious disease a child may return to school without risk:—

Measles.—Three weeks after appearance of rash.

Whooping-cough.—Five weeks, or two weeks after "whoop" has disappeared.

Mumps.—Three weeks after swelling appears, or one week after swelling disappears.

Scarlet Fever.—Six weeks from appearance of rash.

Chicken Pox.—When every scab has fallen off.

FREE PARLIAMENT.

The following resolutions were carried:—

"That the Congress doors be locked during the reading of a paper or address, and only opened at the end of each paper or address."

"That the Government control the prices of groceries for State Bank clients, the same as is done for rations."

"That we ask for a flat rate to be instituted on the railways for all fruit and vegetables."

"That we ask for a bush box library to be available for Bureaux in outback districts, and that books on special subjects be made available to members on request."

"That the Education Department be asked to send doctors and dentists to small country schools."

"That the Welfare Department be requested to send the Baby Health Train on broad gauge lines in the outback districts."

"That the President of this Congress or a proxy be asked to give a wireless talk to members once a month on matters of interest to Branches, so that each Branch may be interested in the doings of other Branches."

CONFERENCE OF WOMEN'S BRANCHES AT PINNAROO.

THE WOMEN'S BUREAU.

[MRS. PEARCE, Parilla.]

The Women's Bureau to all appearances has come to stay. There are many reasons for its popularity, the chief being that its members are united in a common interest, irrespective of class or creed.

Each member has a desire to learn, and those who are in a position to teach do so in a spirit of comradeship and, as is the case in most things of a community nature, the members putting most into it get the most out of it.

One has only to read the reports of the Branch meetings in the *Journal of Agriculture* to realise what a wonderful scope of subjects are brought under discussion month by month. It almost seems impossible to think of something new, yet the work goes on and interest grows.

A large factor in the popularity of meetings are demonstrations. A number of busy housewives with an over abundance of tasks always at hand cannot sit down and study textbooks on subjects that interest them, but enjoy greatly meeting together, and when they can see things done in an atmosphere of relaxation with the social interest added they receive benefit in many ways.

As in all community organisations membership entails responsibility, and the successful Branch is the one with the greatest number of members working.

In these days of depression the Bureau makes a stronger appeal than when money is plentiful. The average housewife is eager to save, and her interest

● FULL MOON.

is roused when she can learn how to make dishes of a tempting nature with very little cost, how to cut out and fit a garment creditably, and how to decorate her home.

Inter-branch visits are also very helpful to stimulate ideas, and the social side is strengthened thereby. The Annual Conferences bring in the expert touch, and much can be learned by those with eyes and ears to see and listen.

One realises in attending the local Agricultural Show and taking notice of the Bureau Exhibits, how much of the artist there is in numbers of the members. This also applies to cooking competitions. Powers that would otherwise lie dormant are brought out to please the eye and stimulate the brain of the observer.

The cultivation of flowers is also another phase of Bureau work, and nothing helps to make a home look more attractive than the addition of a garden.

To put it in a nutshell—the Women's Bureau is a means whereby its members may became educated in the practical, theoretical, social, and artistic sides of home life, and as such is recommended to all who are interested enough to consider joining its ranks.

SECRETS OF SUCCESSFUL SPONGECAKE MAKING.

[MRS. G. BECKMAN, Parilla Well.]

A sponge, if well made, should be one of the lightest and most deightful cakes. To be successful care must be taken in measuring the ingredients, mixing, and baking. The ingredients for a sponge—particularly the eggs—should be fresh and as cool as possible, and the mixing light and thorough. The beating of the eggs can be more effectively done if the whites and yolks are beaten separately, then mixed together, and the sugar added gradually while beating them. This method makes it possible to work up the sponge more quickly.

When adding the dry ingredients, great care should be taken to see that the mixture is neither over nor under mixed. Over mixing and the addition of too much flour makes the sponge tough. Under mixing gives the sponge an uneven texture, and it will possibly be sticky or sugary in appearance. A perfect sponge should not be full of "airholes." It should be fine and close in texture, and very light and spongy.

In baking, a very even, moderate heat is essential. Too slow cooking makes a sponge dry, too fast an oven will cook the sponge on top before it has a chance to rise properly. To test the oven for sponges, sprinkle a little flour on a tin or piece of white paper, and place in the oven in the position in which the sponge will be cooked. Leave it for five minutes. If it turns a golden brown in that time the oven is ready for use.

The even heat of a wood stove is very suitable for cooking sponges. To prepare tins for sponges grease well with butter, then sprinkle with a mixture of equal quantities of flour and castor sugar. Shake off any of the mixture that does not adhere to the tins. If the sponge tins are shallow it is advisable to put a collar of greasy paper around the tins. Prepared in this way the tins give a smooth and browned surface to the sponges.

RECIPES.

Light Sponge, No. 1.—Take 3 or 4 eggs, ¾ cup sugar, 1 cup flour, 4 tablespoons milk, 2 tablespoons butter, 1 teaspoon cream tartar, ½ teaspoon carb. soda. *Method.*—Beat eggs and sugar for 15 to 20 minutes, stir in cup of flour. Boil milk and butter, add cream tartar and soda, boil for 1 minute. Stir into eggs and sugar lightly and quickly. Pour into prepared sponge sandwich tins, and bake in a moderate over 15 to 20 minutes.

Cream Sandwich, No. 2.—4 eggs, 1 cup each sugar and flour, 1 teaspoon baking powder, pinch of salt, 4 tablespoons boiling water in which is dissolved 1 tablespoon butter. *Method.*—Beat whites and yolks separately for 10 minutes, then together for 10 minutes, add sugar, and beat until thick and frothy. Add flour

and baking powder, and lastly stir in boiling water and butter. Bake in sandwich tins for 10 to 15 minutes. Spread with raspberry jam and whipped cream.

Brown Sponge, No. 3.—4 eggs, ¾ cup sugar, 1 cup flour, ½ teaspoon carb. soda, 1 teaspoon cream tartar, 2 teaspoons cinnamon, 1 teaspoon each cocoa and butter, and ¼ cup milk. *Method.*—Beat eggs and sugar until thick and frothy, sift flour, cinnamon, cocoa, and rising together, stir in very lightly using a knife, then add boiling milk with butter melted in it. Bake 15 to 20 minutes in a moderate heat.

Cream Sponge, No. 4.—4 eggs, 1 scant cup sugar, 1 slightly rounded cup flour, 1½ tablespoons cornflour, 3 tablespoons hot water, 1 teaspoon cream tartar, ½ teaspoon carb. soda, 1 tablespoon each melted butter and cream. *Method.*—Separate whites and yolks of eggs, beat whites stiffly, beat yolks well, add whites, then beating vigourously add the sugar very gradually. Beat until thick and creamy. Dissolve soda in the hot water, and pour this down the side without stirring. Mix melted butter and cream, add without stirring. Sift flour, cornflour, and cream tartar, and with a tablespoon mix ingredients lightly together until completely blended. Pour in well-prepared sandwich tins, and bake in a moderate oven for 18 to 20 minutes. Turn out carefully on a sieve, and when cool put together with a suitable filling.

Swiss Roll, No. 5.—3 eggs, ¾ cup sugar, 1 cup flour, ½ teaspoon carb. soda, 1 teaspoon cream tartar, and 1 tablespoon cold water. *Method.*—Sift flour, soda, and cream tartar together. Beat eggs and sugar until thick and frothy. Add flour, stirring lightly, then add water and mix well. Put in a flat tin which has been lined with buttered paper. Bake in a moderate oven. or until when pressed with the finger no mark is left. Turn out on to a cloth sprinkled with castor sugar, roll up quickly, unroll, spread with warm jam, and roll up again. All sponges should be beaten at least 20 minutes to ensure success.

VARIETY OF SMALL MEAT DISHES.

[MRS. R. J. BILLING. Parilla Well.]

When preparing the midday or evening meal and a small dish as well as a joint of meat is required for the table, the following recipes will be found useful and very nice.

Beef Olives.—1½lbs. thinly sliced beef; lay on each slice a very thin slice of bacon. Prepare a seasoning of bread crumbs, thyme, rind of lemon, pepper, and salt. Put a little on each slice of beef, roll up, and tie with cotton. Place in saucepan, add a little onion, and cover with water. Simmer for 4 hours. Half an hour before serving take off cottons, and thicken stock. Put back to heat. Dish with toast around it. Add about a dozen olives if cared for.

Indian Curry.—Peel and slice 4 medium-sized onions. Brown in a pan with 2 tablespoons butter and 1 tablespoon dripping, stirring often. Then add ½ cup cocoanut which has been soaked in a little milk. Let brown, then add 1 cup milk, 3 teaspoons curry powder, pepper, and salt. Peel and halve about 5 hard-boiled eggs, lay them on the dish of curry, serve hot with plain boiled rice. Some meat cut into squares may be used in the place of eggs.

Luncheon Dish.—Cut 2lbs. steak into very thin slices, mix 1 cup of breadcrumbs with sago, salt, and pepper to season, 2 fair-sized onions sliced. Place a layer of meat in the bottom of dish, then a layer of finely-cut onions, and finally a layer of breadcrumbs and seasoning. Repeat this until dish is full, then pour over all 1 cup water, place on top a few slices of bacon, cover with a plate, and bake in a slow oven for 2½ hours. Any meats can be done in this way.

Brawn.—1 shin of beef, ½lb. bacon, 2 or 3 sheep's tongues, water, salt, and pepper. Wash and chop shin bone into pieces about 6in. long. Remove marrow from bone, and cut off bacon rind. Place shin, bacon rind, and sheep's tongues in a large saucepan, cover with cold water, and add salt and pepper. If liked, a bunch of herbs can be tied in muslin and added. Bring all to a boil, and simmer until gristle is tender and meat leaves the bones. Lift out, cut meat and

gristle into small pieces, skin and cut up tongues. Return to saucepan, keeping back the bones, rind, and herbs. Bring to boil, and cook for a short time to reduce the liquid if necessary. Pour into moulds or basins, and allow to set firmly. Remove any fat from top of mould, turn out, and garnish with parsley. If a pig's cheek is used with the other ingredients it is an improvement.

Meat Paste.—1lb. beef with a little fat. Cut into large pieces, and steam in a jar or basin for 3 hours. Put through mincer 3 times, add gravy, 1½ teaspoons each grated nutmeg and pepper, and 2 teaspoons salt. Mix well together and put in small jars.

Steak and Apples.—2lbs. steak, 4 apples, ½ cup breadcrumbs, 1 tablespoon melted butter. Peel and slice apples, make some cuts in steak with a sharp knife to keep apples in place. Season with pepper and salt. Roll up and tie to keep all together. Brush all over with melted butter, and roll in breadcrumbs. Put into a greased paper bag, and bake 1½ to 2 hours in a moderate oven. Serve with brown gravy.

Stuffed Loin of Mutton.—Remove the bones from a loin of mutton, then beat the meat and trim neatly. Lay any good trimmings in the centre of the piece, and season well with pepper and salt. Prepare some veal stuffing, and place it in the meat where the bone was removed. Roll up and tie securely. Bake in the usual way, and serve with gravy. A green vegetable or tomatoes and baked or mashed potatoes can be served with meat.

THE HOME GARDEN.

[MRS. G. PEARCE, Pinnaroo.]

There is nothing that adds so much to the attactiveness of a home as does a garden of gay flowers and shrubs. The fences used as breakwinds—so necessary in open spaces—may be made beautiful with creepers and twining plants.

This is quite a simple matter when a good supply of water is laid on to the garden, but the flower lover whose home is in a low rainfall area, and with water either unsuitable for a garden or too far away, is often discouraged by her first attempt to make a garden and grow her favourite flowers. Still it is possible for almost everyone to have a few flowers during the greater part of the year if care is taken to choose those which need least water. Of course, every drop of usable water must be saved. Even the soapiest water can be utilised if a trench about 9in. to 12in. is dug beside the row of plants, filled almost full with charcoal and coarse sand, and the water poured into this.

A row of chrysanthemums do quite well with this treatment. If two rows of chysanthemums are planted about 18in. apart and during September or October a few seeds of cosmos and miniature sunflowers are planted between the rows, they will flower before the chrysanthemums. Snapdragons, calendula, linaria, larkspur, stocks, and wallflowers are all easily grown, and will stand dry conditions better than most flowers. Never allow any flower to go to seed, unless you wish to keep the seed, and the plants will flower longer. The calendulas will supply winter blooms if planted early. Marguerites are hardy; they bloom for a long period, and are well worth growing if space and water are sufficient.

It is surprising how much can be grown in a 12ft. square. Plant fairly close and give a light mulch. If it is desired to grow a few less hardy flowers, plant the seedlings in tins and bury these near a taller plant. In this way they may be given special care, and yet not robbed by the stronger plants. Cold tea is splendid for watering these favourites.

Geraniums make a bright show, and are good subjects for the gardener who has little time to spare. I prefer them, however, as outdoor pot plants in any shady place.

Daffodils and freesias are the best bulbs. They need not be taken up every year. In fact, they do better if left undisturbed, and are not at all harmed by being watered while dormant. Exhibition blooms cannot be expected by these methods, but we should seldom be without a few flowers for our homes.

WHAT IS THERE TO BE GAINED FROM THE ANNUAL AGRICULTURAL BUREAU CONGRESS?

[Mrs. E. J. Sands, Pinnaroo.]

I have been trying for some years now to ascertain from which source we get the greatest benefit—if from our own papers with the discussions of our own members who live in the same districts, work with the same material under the same conditions and who experience the same difficulties, or do we derive the greatest amount of knowledge from professional speakers who give us the results of years of experience, who work in different districts, under totally different conditions, and who have the experiences of professional experimenting in other States in addition to their own home districts?

We have all the experiments and practical experience and the worked-out theory. We gain quite a lot of good knowledge from Mrs. Brown's paper on cooking, how to cure a pig, and how to manage the home, dairy, poultry run, make jams and preserve fruit, home dressmaking, home nursing, and many other subjects needful in everyday life, but it appears that all of these subjects, handled by the amateur, lack such a lot of knowledge that is really essential to the subject if it is to be the success it undoubtedly should be. Therefore, take hold of every advantage, each moment of time, lectures, practical demonstrations arranged by the Agricultural Congress—such as Farmers' Union factory, with its butter, cheese, egg, egg pulp, milk and bacon departments which gives more help in a few minutes than can be gained by papers; the visits to Faulding's, Roseworthy, Waite Research Institute, Unley Central School, Better-farming Train, Babies' Health Centre, which all give practical demonstrations and make our job very much easier to go back to.

Let us look at what can be learned from lectures by professional speakers such as Miss Campbell, Mrs. Dolling on "New Zealand," Mrs. Morriss on "Education," and "Speargrass" on "Gardening." Doctor Halley gave us the professional side of "Home Nursing," and Dr. Constance Davey spoke on different types of children and how other countries are dealing with them.

Compared with these professionals, our papers lack the theory of all these subjects, and no one can work on any job, be he professional or labourer, business man or otherwise, unless he or she has the proper theory to start on.

Country conferences do more than words of mine can tell for each district. I hope all will try and attend the Agricultural Congress, and I hope to see the time when those women who go from each branch to represent its members will attend each session and carefully take notice of all that is to be learned from the papers read and bring it back to the home branch. It seems a pity that a different member cannot be sent each year. Those that have never been to a Congress have certainly missed a great opportunity. The visit paid to the Unley Central School was an eye-opener which Bureau members will never forget. It would take too long to describe all that was seen there.

My opinion is certainly definite on the subject that we gain very much more from the Agricultural Congress by giving our whole attention to the programme set down by professional men and women than by reading our own papers that can be done at our own monthly meetings. There we can use the saying, "Discussion is the life of the Bureau," and discuss subjects to their fullest, and after the discussion we will still need a professional to put us on the right track.

We cannot value too highly the ability of Mrs. Hammatt who has presided for so many years. She has always given willingly of her experience as a housekeeper. She never absents herself from a meeting, and is always so good at helping others.

CARE OF THE HOME.

[Mrs W. Threadgold, Parrakie.]

There are many methods of taking care of the home, and these may be very varied. Take for instance the town housewife, who has only her home to think of;

then there is the farm houswife who has to do numerous tasks outside before she can give any attention to housework.

The main thing about a home is to have the rooms built as conveniently as possible, and to have water laid on to the kitchen, washhouse, and bathroom. The work can be done more quickly, and one does not feel so tired as they would if the water had to be carried. I always try to start the week by doing the washing and ironing, and have the middle of the week free for gardening, sewing, &c. Where there is only one woman to do all the work it is a good plan to clean rooms that are not in constant use in the middle of the week. That is easier than having all the cleaning to do at the week end when there is extra cooking and numerous other duties to do.

When spring cleaning I do one room thoroughly each day, and choose a week before the busy season if possible. When there are a number of windows to clean do a few at a time. When washing blankets, doing one or two on washing day is not so strenuous as doing them all in one day. A separate case on mattresses saves a lot of work and time; these are easier to take off and wash than having to empty and refill the mattress.

Kerosene is useful in many ways for household duties; a little added to the water when washing linoleum helps to give it a polish and also preserves it. In homes where there are small children and there is danger of them falling on slippery floors, instead of polishing rub over the floors with a cloth to which a little kerosene has been applied. Another suggestion is to mix 2 cups of kerosene and 1 cup of linseed oil, shake both together, and apply to the floor with a cloth or mop. A few drops of kerosene added to the copper when boiling clothes will help to whiten them. Windows and mirrors can be cleaned very easily with Bon Ami rubbed on with a damp cloth and when dry rubbed off. Spraying rooms with Fly-tox and closing them for a while helps to keep moths and silverfish away. Spray skirting boards well and all corners; also wardrobes, drawers, and cupboards. Petrol sprayed inside of instruments will help to keep moths out of them.

Blowflies are another pest, especially in springtime. If a wire screen is made and put on top of the chimneys it will keep quite a lot out of the rooms. Chimneys can be cleaned by pulling a pine branch up and down. A good way to remove finger marks from furniture is to sprinkle a few drops of mop oil on a damp cloth and polish with a chamois.

The kitchen is the main room in the home as a woman spends most of her time there, so have it as bright as possible. I prefer a fair-sized room with white walls. In the evening if the ashes are cleaned out of the stove, the fire set, and the table set ready for breakfast, it is a good help in the mornings, and the menfolk are not delayed in getting to work.

The best method of arranging the home is to have the meals at regular hours and plan a certain amount of work for each day. The outside appearance of a home should receive just as much thought as the inside. Shrubs, bright flowers, and a few pot plants all help to make the surroundings attractive, not to mention fruit trees and the ever-profitable vegetable garden.

THE PLACE OF HUMOUR ON A MALLEE FARM.

[Mrs. Herbert, Parrakie.]

Before coming on to a farm in the mallee, if I had believed reports given by those who had had unhappy experiences, I should have doubted if there could be such a thing about it as humour. Like an old lady at the zoo, on first seeing the giraffe and looking up its long neck to its funny little head, she solemnly declared, "There aint any such animal." However, we do know that even when things are difficult there is still a place for humour, and if we did not believe it probably we should not have come.

Humour is a mental quality something like wit, but depends for its effect rather on kindly human feeling than on brilliancy of expression. It is a quality that

gives to ideas a ludicrous or absurd turn. We know it probably among members of our own families. But not all have it, for in that form it is a gift. But add "good" to it—"good humour"—and all can have it, for it means cheerfulness and a happy temper.

I do not see any place for humour at the expense of other people's feelings. This may be wit, not humour. There is no place for fun about physical failings or peculiarities on which they are probably sensitive. There is no place for humour about the facts of life, especially before our little folk. No repeating of youthful questions, especially in their hearing, about the beginnings of their own life. That is a something for you to answer them as wisely as you may—a secret between you and them, and to have told them before the vulgar world gets hold of them.

Now what would life miss on a farm or anywhere else if we had not our jolly people that can turn a laugh in a bad time. Charles Dickens and his Mark Tapley who thought it no credit at all to be lively and gay when things were bright. But when Martin Chuzzlewit got to America and bought a farm from a city plan and went out there with Mark and found it a fever-stricken swamp with neighbours ill or dispirited, he began to shine brightly. He was up against something, and now was the time to be jolly. But he *acted* the jolly part, too, and helped one and all.

We cannot all say funny things or shrug our shoulders in a funny way, or make a funny face, and such folks are a gift to our sometimes rather drab old world. I remember reading, "Some folks make more friends coming into a room than others do so by long and faithful service." It is so, and quite often the popular ones are the ones who can do something humorous.

On a farm there are special times that call for a display of good temper—when the cow kicks over the bucket of milk, when the horses get out of the yard by pushing down a weak post, when other people's animals like the look of your wheat or oats—best of all, when the animals get sick, when we want to do a job that is past our strength and have to see someone else—so kindly to the rescue—doing it *not* as we would. When the flies come in millions and get into all the food and will not leave our arms and faces alone—these and many others are times that need a bit of good humour to help us over.

I believe singing and even whistling is a good help. It encourages cheerfulness, and heartens others. Perhaps you say it is not very sweet music. Well, there are lots of birds, and all are not nightingales. Even the crow and the sparrow join the chorus, though I confess we must forget for a moment the designs they have on the lambs and the wheat.

There are times probably when all feel low spirited, and perhaps our Bureau may, with its sociability, help a little, for we are rather lonely and very busy women, and cannot often meet. But a merry heart doeth good like a medicine, and if it is not in our power to make others laugh at troubles or difficult situations perhaps a laughing, good-humoured spirit may radiate through our own lives, and give us the glow to halve the troubles and double the joys of life on a mallee farm.

CONFERENCE OF UPPER NORTH WOMEN'S BRANCHES.

Mrs. M. B. Genders presided over an excellent attendance of delegates from the Nelshaby, Belalie, Morchard, Wepowie, Willowie, and Wilmington Branches. Ladies were also present from Port Pirie, Jamestown, Tanunda, Murraytown, and Hammond.

Miss E. Campbell of the Education Department addressed the delegates on "Food Values," and the following papers were read and discussed:—

NEEDLEWORK.

[Mrs. E. L. ORCHARD, Belalie Women's Branch.]

Do we ever think, when we sit outside on a sunny afternoon or by the fire on a dull one to do our mending or knitting, that our work basket and everything in it has a history, some of it very interesting. Even the humble but useful pin has evolved from something quite different from what we use every day and has been manufactured in England since the Sixteenth Century. Pins made of bone were used

by savage races, bronze pins have been found among the relics of the later stone age, and until the end of the Fifteenth Century, women used skewers to keep their clothes together. The term "pin money" originated from the custom of people giving gifts of a collection of pins or the equivalent in money. A pin of bronze, very slender and bent in such a manner that its point is caught against the head, has been found, which makes collectors think that the safety pin or its ancestors originated in Central Europe about the year 1000 B.C. Modifications of this type of pin apparently used as we now use brooches for decoration, were found among the possessions of the people of early Europe.

Embroidery—obviously achieved with needle and thread—is to be seen on ancient Egyptian garments, and iron needles have been found in Egypt and Rome, but other than that the origin of needles is lost in antiquity. We read delightful passages which deal with spinning or needle craft in many of our most valued books, and they often throw light upon a character or situation which is more illuminating than many lines of descriptive matter. English writers of the past generation, speaking of the most essentially and beautifully feminine of crafts, always do so in connection with the needle and the fingers. About the year 1500 needlework exhibited showed that Biblical subjects were more usually chosen than any others in all types of embroidery; for instance, the whole story of the Flight into Egypt is told by needle-pictures on old tapestry wall hangings.

Needlework is an all-absorbing subject, be it mending of working clothes or the creation of some exquisite ornamentation or garment. Ruskin places needlework first of the six queenly and muse taught arts, the others being writing, pottery, sculpture, architecture, and painting.

Morality may sound a big word to use in connection with such a homely, every day experience as needlework, and yet in our grandmothers' days careless, slovenly sewing was considered a disgrace of the most serious kind, and it is certainly an unfailing index of unlovely qualities. Directly one begins to use a needle, a regular character-chart is started upon, and the very first indication that appears is the degree of patience possessed by the worker, and there is no need of an elaborate piece of work to test this quality. The sewing on of a button or a mended tear is sufficient. I wonder how many of us feel sometimes there really is not time to do an insignificant bit of mending properly, and proceed to "cobble up" the tear with any cotton that is near at hand or catch the button to the coat with half a dozen hasty stitches. And all through there is the uneasy sense of guilt, as if one has quite consciously offended against the standard of refinement. On the other hand, what a delightful sense of peace and satisfaction in right-doing comes when the temptation to be in a hurry has been resisted and the threads of matching material have been carefully unravelled, a fine needle chosen, and an almost invisible darn accomplished.

The homely craft of needlework becomes an accessory in our individual development, and after all, impatience and laziness are handicaps in every walk of life; so, too, is contentment with work of an inferior standard, work which is poor and hasty and that which, if we cared to take the time, we could improve. The great thing in needlework is to feel we can express our own ideas in the stitchery that is not all darning or mending. Even a tree or bird crudely drawn to decorate a child's overall, if our own idea, is a step in the right direction to creating something that no one else has exactly like it. There are so many purposes to which one's knowledge may be applied, and the plainest piece of work can become a thing of beauty if the stitching is good and the embroidery evenly done.

Many people like to make presents of their handiwork when birthdays come around, and how much more is the work appreciated when the time and thought of a friend have been lovingly spent upon it. A present should be a luxury, a little extra that will add to the pleasure of life, a gift beautiful to look upon, but useful. Embroidery is the decoration of the useful, a gay touch of colour turning everyday articles into treasures of art. In hand-needleworked gifts, the chief cost is labour, and therefore the willing giver can be more ambitious. The machine-made article, however perfectly

finished, does not satisfy the craving for the personal touch or the desire that the gift should be made exclusively for the recipient.

Attention to detail is always important, and good tools are as necessary as good work, and particularly the needles should be the correct size for the threads in use; if the eye is too small, a frayed thread results, and if too large a hole is left in the work that is sometimes hard to fill. Scissors should be sharp and of a size suitable for the material in use. It would take many hours to describe in detail all the types of needlework that are used at the present time, but amongst the most popular are tapestry and knitting. One of the greatest revivals in the history of embroidery is the present vogue for tapestry on canvas, that beautiful art which was practised in England as far back as the Fourteenth Century, and has such an appeal to the busy, modern woman who finds it a soothing and fascinating relaxation for the precious leisure hours. We are living in an age of expression, and tapestry has an atmosphere of romance about it that makes it welcome in any home, old or new. Cushions, chair seats or backs, a fire screen, footstool or a handbag can give the maker of needleworked tapestry, who would express her own personality, scope and possibilities second to none.

For those who prefer it, knitting can fill all available spare minutes in the day, and in this, as in other needlework, attention should be paid to the sizes of needles used with particular threads and according to the garment to be made. For instance, baby clothes should be worked more loosely than other articles, because naturally they are laundered more frequently and will eventually shrink with continual washing. These hints about knitting needles may be useful: For looser knitting bone needles are best; when a flaw does appear it should be smoothed with glass paper and the points should never be too sharp; for heavy, large garments, enamel coated steel or aluminium needles do not bend as do those made of celluloid.

All women should learn to knit. Many beautiful articles as well as useful ones can be made with knitting needles, and it does not require such good eyesight as fine embroidery or crochet work. Some women can knit and read at the same time; knitting is a restful occupation for the tired housewife, a great boon for restless hands and tired brains, and for old ladies who can no longer see to make the delicate stitches in other needlework.

Every mother should consider it her duty to teach her daughter to knit; if she does not make use of the accomplishment in her younger days it will be a great comfort in old age. For what is more pitiful to see than an old lady sitting through the long winter evenings with nothing at all to do? Plain needlework is the first essential to learn; besides its practical value, it teaches neatness and accuracy.

For the sake of one's health, it is important never to sit in a stooping position; always sit so that the light comes over the shoulder, and avoid working on dark materials in an artificial light.

The art known as needlework can be summed up as a knowledge of how to make the best use of needle and thread.

INFANT'S LAYETTE.

[By SISTER GURRY, Belalie.]

The layette described is within the means of most mothers and comprises all the essentials. Mothers may, of course, add additional garments, according to their means.

Clothing needed for new babe:—4 gowns or frocks, 3 or 4 petticoats, 3 singlets, 3 binders, 2 or 3 dozen napkins, 2 pairs bootees, 2 coatees, bunny rug, &c. The amount of baby's clothing should be regulated by the weather, remember to clothe baby according to the temperature of the day.

Materials used for baby clothes should be both for health and economy. The essentials to remember about all baby clothing are:—

1. To see that the garments are light, warm, and non-irritating.
2. To provide for warmth and air without undue weight or multiplicity of garments.
3. To see that they are made in such a way as to ensure easy washing, drying, and ironing.

4. Have no constricting bands which hamper development.
5. Have no undue double thickness of material, which is difficult to dry quickly.

A young baby does not possess the ability to regulate its own body heat, therefore his temperature varies according to the surrounding atmosphere. Cold air will not injure baby provided he be suitably clothed. Clothing should be light and warm, and if possible, suspended from the shoulder—the best a mother can afford. Flannelette is most unsuitable; it is too heavy and is inflammable. Most babies, however, suffer much more from being overclothed than underclothed, and a very great exception is the feet. It is surprising how often a baby's feet and legs are uncovered even in cold weather and allowed to become chilled, therefore it is most necessary that young babies should wear bootees. A good rule is: In winter keep the baby warm, but not hot; in summer keep him cool, but not cold. The signs of overclothing are excessive heat, restlessness, and irritation of the skin, which sometimes leads to prickly heat or eczema, it may also cause diarrhoea. So much clothing prevents freedom of movement for the limbs—baby cannot have enough active exercise from kicking if overclad and this may give rise to constipation. Baby's clothing should not be tight around any part of the body.

The Binder should consist of light flannel, 4in. to 6in. in width and about ¾yd. to 1yd. in length. This should not be wrapped around baby too tightly and should be held in position with a few stitches or 3 small safety pins. The binder is frequently left on for some considerable time after it has served its purpose; this is a mistake, it prevents the muscles of the back and abdomen from developing properly and so hampers deep breathing. Baby should be allowed to develop normally and naturally, and for this reason the binder should be discarded as soon as the dressings on the cord are no longer necessary.

The Vest may be made of silk and wool or soft baby wool, so that it will not irritate the soft skin of baby. A wide piece of tape should be stitched on the front of the vest so that the napkin can be pinned to it, thus preventing any space between the vest and napkin.

The Napkin should be made of soft swan skin or good flannelette, and care should be taken when putting on the napkin, it should not be drawn too tightly or made bulky between the legs, this causes discomfort, deformity such as bandiness, and contraction of the pelvis. A sufficient number should be supplied so that clean and dry ones are always at hand; they must always be changed when wet. Never re-dry and use again. Do not use soda or blue for washing. Attention to these details will largely prevent chafing. Never put rubber pants on a baby, they are most injurious to its tender skin as well as its general health. A pair of pilchers, knitted, should be worn outside when baby is being carried; a very suitable napkin protector can be made from double flannel.

The Petticoat should be made of loosely woven flannel or same material as frock, make same length as frock, or in other words, long enough to cover the feet—they can always be shortened later. Allow 1¾yd. of 30in. material for each petticoat.

The Frock should be made same length as petticoat, of soft material—radianta, viyella, winceys, &c. Light knitted frocks are useful for colder weather. Allow 1¼-1½yd. of 30in. material for each frock.

The Coatee.—Use any materials suggested for frock—flannel or knitted ones.

The Nightgown.—Any soft material, cheap flannel, wincy or viyella; make long, as pattern. Take 1¾yds. of 30in. material for each nightgown.

The Bootees.—These can be made of scraps left over from frocks, &c., or may be knitted. Baby's feet must always be kept warm. Mothers are reminded that it is seldom necessary to make the full number of bootees, bibs, bonnets, &c., as these garments are often given to baby as presents.

The Bonnet should only be worn when the baby is outside on cold or windy days.

Shawls.—One large shawl for outdoor use should be provided, also two smaller ones or bunny rug or blanket for use when lifting baby from his cot and taking him from one room to another.

Bibs.—Seldom used, but very often handy. They can be made from scraps.

SOAPMAKING.

[Mrs. C. A. Brown, Eurelia.]

Soap should be boiled in order to obtain the best results. Soap made by the cold method does not lather satisfactorily, and it is very harsh on the hands. The method indicated below yields a soap of good colour and even texture.

Save the fat skimmed from the corned beef water, soups, stews, and that which is of no further use for frying, &c. During the cooler weather all fatty trimmings from cooked or uncooked meats may be put into an old cake tin, and when the oven is hot for baking it can be rendered down without extra expense. When making this soap no more than the quantity indicated should be made in a kerosene tin at one time, because it boils over very readily. Care must be exercised in the handling of the caustic soda as it is a powerful corrosive.

Put all the fat into a vessel (unless it is quite clean and strained), and melt it with a quart of water. Strain through a coarse cloth, it is more effective than a colander. Allow to become hard, and the dirt and salt and much discolouration will be found in the water. Lift the fat, scrape off the layer of dirt, and weigh it.

To Make Soap.

Put 1lb. caustic soda into a kerosene tin and add 6 quarts of water. Avoid getting the dust or fumes into the nostrils or lungs. Add ½lb. resin, 1 packet lux, 1 tablespoon borax, and 7lbs. fat, carefully. Bring to a boil and be very careful it does not boil over. Stir occasionally. Allow to boil slowly for 2 hours. Remove from fire, stir in 1 teaspoon of citronella and leave in the tin overnight, or pour int a box lined with wet calico. Turn out next day and leave to dry for a week or two before cutting into bars. It will be ready for use in about a month, though the drier the more economical it will be. If preferred, all dry ingredients may be put into the tin first and the water poured over them. The better plan is to let it stand all night before making and it is less likely to boil over.

A Tested Recipe.

Put 1lb. resin and ¼lb. borax in a copper with 11 pints of hot water. Boil until the resin is soft and stringy. Melt 6lbs. of fat and pour into the copper. Dissolve 1lb. caustic soda with 3 pints of warm water. Use a large tin or enamel vessel for this purpose. While it is bubbling pour into the mixture in the copper, stirring all together. Add ½ cup of liquid ammonia and ½ packet of lux flakes. Boil for 5 minutes, then pour into moulds or leave in the copper to set. The soap is of a white colour when first made. Leave it stand to dry for a month before using. It will then be of a pale yellow colour.

Papers from Nelshaby Women's Branch.

WOOL.

There are many ways of using the woollen coat from the sheep's back. In these days of depression and hard times it behoves every one to make money go as far as possible. Of course, this year wool is much dearer than it was last year. This year knitted garments are very fashionable, and as well as being warm, they can be very smart. Jumpers, caps, coats, gloves, scarves, bags, pullovers, dresses, and quite a number of articles are knitted in dozens of different shades and designs.

Jumpers, for instance, can have cowl fronts, fancy collars, puff sleeves, long sleeves, short cuffs, long cuffs, elbow puffs, leg of mutton sleeves, wing sleeves, in fact, the same type of sleeve as a frock. Jumpers are either short or long with a belt. Raglan sleeves make a well fitting jumper. Caps are made in colours to match jumpers, some are straight with peaks at the top, some drawn down over the right eye, some shaped at the top. Coats ar made in a variety of styles—long swagger coats, short coats, coats with belts, raglan sleeves, cardigans with and without collars. Caps, scarves, gloves, and bags knitted in the same colour and design make very nice sets.

Evening capes can be knitted with wool (2-ply) in a plain or fancy stitch. Bridge coats are very easily knitted. All these garments are very cheaply made. Pullovers,

socks, scarves, and gloves are made for men, and for the babies practically everything that they wear.

Babies' clothes should be knitted in either babies' wool or 2-ply wool, and done on a fairly large needle (say size 9). If they are knitted too finely they shrink more easily than garments knitted loosely. For bigger children whose clothes have to be tubbed a lot, a cheap wool is best, it does not shrink so much.

Men's pullovers and cardigans look better if knitted in a 4-ply wool. When knitting a garment, it is best to use your own directions because what will fit one person may not fit another when knitted. Very few people knit alike. Some people say, "Oh, yes, these directions will fit me, I'll just use a larger size needle." Of course, when the garment is finished, it may fit the person it was intended for, but look how loose the tension is, and the smartness is gone.

Size 10 needle is the best to use for 4-ply wool, size 11 needle for 3-ply wool, and size 12 needle for 2-ply plain knittings. If you are a tight knitter, use a size larger needle; if a loose knitter use a size smaller. For 2-ply lacy stitch jumper, size 10.

If you do not know how many stitches to cast on for a jumper, cast on about 30 stitches, and knit 1 row and purl 1 row for about 2in. Then measure the number of stitches to the inch. If the tension is 10 stitches to the inch and you want to knit a piece 10in. wide, you will want 100 stitches. When shaping a jumper do not guess the size but take the bust, chest, length of jumper from neck and armhole, and length of sleeves. On no account stretch knitting to the desired shape. When knitting a jumper or any garment always knit the back first. It is safest to commence sleeves from the top. If knitting a jumper to the throat make the front neck 1½in. lower than the back. Always be careful when putting a jumper together, sew all straight seams by hand. Sew shoulder seams by machine and sew sleeves in by machine. If a striped jumper, see that each stripe meets.

For the bottom of jumpers, always cast on with the thumb and 1 needle. Do not knit into the back of the stitches. If knitting a hem, knit on the stitches with 2 needles, do not knit into the back of the stitches. When you have knitted twice the depth of the hem, as you knit pick up a stitch from the first row. For button holes, cast off, say, 4 stitches, in the next row cast on 4 stitches, in the next row knit into the back of 6 stitches. Always count the cast on stitches as a plain row.

If you have old jumpers that are finished, unpick them, knit into squares about 4in. square, or any odd balls of wool, any colours will do. Join together after the fashion of a patch-work quilt. Knit these squares with double wool. Cosy blankets for baby or even for larger beds can be made in this way. Last winter I made a blanket for a three-quarter bed, all knitted with double wool.

RECIPES.

[Miss De Silver.]

Iced Currant Fingers.—¼lb. butter, ½ teaspoon baking powder, 2ozs. sugar, 1 egg, ½lb. flour, 1 tablespoon milk, salt, 2-4ozs. currants. *Method*: Sift flour and rising, rub in butter, add sugar and currants. Mix egg yolk and milk together, and stir in flour to make all in one lump. Roll out thin, beat egg white well, stir in 4ozs. sifted icing sugar gradually. Spread thinly over surface of biscuit, cut in fingers and bake in moderate oven 20 minutes (400°).

Short Bread Creams.—3 eggs, ½lb. butter, ½lb. sugar, 1lb. S.R. flour. *Method*: Cream butter and sugar, add beaten egg, then flour. Roll out, cut into rounds. Icing: Mix icing sugar with a little lemon juice and melted butter, put between two biscuits.

[Mrs. Noble.]

Wholemeal Crisps.—1 cup sugar, 1 cup butter or cream, 1½ cups of wholemeal, 1 cup flour, 2 teaspoons of cream tartar, 1 teaspoon carbonate soda, enough milk to mix; roll and cut in shapes (moderate oven).

Currant Fingers, Iced.—¼lb. butter, 2ozs. sugar, ½lb. flour, pinch salt, ½ teaspoon baking powder, 1 egg, 1 tablespoon milk, 2ozs. to 4ozs. currants. Sift flour and rising, rub in butter, add sugar and currants, mix egg yolk and milk together, and stir into

flour to make all in one lump, roll out thin. Beat the egg white well and stir in 4ozs. of icing sugar, spread thinly over the surface of the biscuits, cut in finger lengths, and bake in oven about 20 minutes (400°).

Stuffed Monkeys.—Paste: 2 cups flour, little salt, 2 level teaspoons cream tartar, 1 level teaspoon soda, 3ozs. butter, 2 tablespoons sugar, 1 egg. Sift flour with rising, rub in butter. add sugar and mix into a stiff paste with well beaten egg, roll out about ¼in. and cut into 3in. squares. *Mixture*: Chop up 1 cup seeded raisins, 1 tablespoon mixed peel, 1 tablespoon sugar, ½ cup sultanas, 1 teaspoon ground cinnamon. Mix all together and put 1 dessertspoon in each square of paste, fold over and press edges together, brush with milk and dust a little sugar over, bake until golden brown (400°).

BISCUIT RECIPES.

[Miss FRANKS.]

Cocochews.—Beat 2 egg whites until stiff, add ½ teaspoon salt and 1 cup sugar a little at a time. Mix with 2 cups corn flakes, 1 cup cocoanut, and ½ teaspoon of vanilla. Bake in a moderate oven for 10 minutes.

Cocoanut Rocks.—2ozs. each corn flour, sugar, flour, butter, and desiccated cocoanut, 1 egg, 1 teaspoon baking powder. Cream butter and sugar, add beaten egg, then dry ingredients.

Rosala Biscuits.—2 cups S.R. flour, ½ cup sugar, ¼lb. butter, 1 egg and yellow of another. Mix dry ingredients, then make stiff with egg and a little milk if needed. Roll out, spread with following mixture. Beat an egg white stiff, add enough icing sugar to make f a, cut into fingers and sprinkle with cocoanut.

THE JOURNAL

OF THE

Department of Agriculture

OF SOUTH AUSTRALIA

VOL. XXXVIII. JANUARY, 1935. No. 6.

Published Monthly by the Department of Agriculture.

Edited by H. C. PRITCHARD.

CONTENTS. PAGE

All communications to be addressed:

"The Editor, Journal of Agriculture, Education Building, Adelaide."

AGRICULTURAL VIEWS AND COMMENTS.

MISCELLANEOUS.

Agricultural Bureau Conferences—1935.

River Murray Swamp Areas, at Murray Bridge (Jervois Branch), Thursday, February 21st (F. P. Baily, Woods Point, Secretary).

Yorke Peninsula, at Kadina (Boor's Plains Branch), March 6th, S. G. Chynoweth (Secretary).

Mid-North, at Redhill, Thursday, March 14th (S. A. Pengilly, Secretary).

South-East (Upper), at Mundalla, Wednesday, March 20th (A. Ross, Secretary).

South-East (Lower), at Mount Gambier, Wednesday, April 10th (G. T. Gurry), Secretary).

River Murray, at Moorook, Thursday, June 20th (S. Perkins, Secretary).

Each Conference will commence at 10.30 a.m. Members of Branches are invited to submit papers and questions for the agenda of the Conference in their respective districts.

Decomposed Oyster Shells as a Fertiliser.

"Koolunga" asks what benefit is land in this district likely to derive from the use of partially decomposed oyster shells?"

Professor A. J. Perkins (Director of Agriculture), to whom this question was submitted, says.—"I realise that a good deal of propaganda on behalf of this material, under the name of calcium carbonate, has taken place within recent years. It has been claimed that this substance would supersede superphosphate and prove very much cheaper. Needless to say, the only value of the substance is the amount of lime in easily accessible form to the roots of plants. It follows that, generally speaking, it is not likely to prove useful, except in those districts which are deficient in lime. This applies to the Hills Districts generally, portion of the South-East, Kangaroo Island, and the extreme southern portion of Eyre's Peninsula, but over the great bulk of South Australian agricultural lands the addition of carbonate of lime would be sheer waste of time and money, as they are already well supplied with lime. I certainly cannot recommend it for the Koolunga district."

Mr. Spafford's Visit Abroad.

In a letter to the Director of Agriculture (Prof. Perkins), Mr. W. J. Spafford (Deputy Director), who is on a visit to other countries, states that during his brief stay in New Zealand the officers of the Department of Agriculture enabled him to see a lot of the agriculture of the Dominion and some of the information he obtained will be included in his report to the Government on his return.

He describes the pastures of New Zealand as "wonderful." He has visited Pure-Seed Stations, Multiplication Plots, and farm pastures in order to investigate the production of pastures and seeds and to obtain first-hand knowledge of the Certification of Seeds Scheme which is being so successfully operated by the Department in New Zealand.

Mr. Spafford was fortunate in being in New Zealand at the commencement of the season for exporting fat lambs. By calling on producers, stud breeders, and slaughter works he has secured a lot of data which when published will prove of great value to our producers. A large area of sea marsh which was raised above sea level by the Napier earthquake is being reclaimed by drainage. As well as reclaiming saline land, the New Zealand Government is bringing into production useless pumice lands, and although the methods adopted are not directly applicable to our State, much useful knowledge has been gained by investigating them.

A visit was made to the Lincoln and Massey Agricultural Colleges. At Massey, a very simple and efficient method of discovering the exact amount of hair appearing amongst the wool of long-woolled sheep has been developed, and breeders are so impressed by it that thousands of stud animals are being tested and recorded. Mr. Spafford thinks that this practice may prove useful to South Australian stud breeders of English sheep and perhaps even for Corriedales and Coarse Merinos.

Seed Wheat from Turretfield.

Throughout South Australia there is difficulty in securing any quantity of first quality seed wheat, and in order to assist in overcoming this disadvantage, the function of the Government Farm at Turretfield during the past two years has been to select and develop pure strains of the best varieties, so that supplies of reliable seed should be available for disposal to farmers.

The plan of improvement and purification adopted, namely, building up from hand-selected ears, is not yet in full operation, as four seasons must elapse before the multiplication process is completed and seed of that selection increased sufficiently to allow of grain being offered for sale.

However, in the meantime bulk purification has been conducted, and good seed of Federation, Ford, Ghurka, Nabawa, Ranee 4H, Sultan, Sword, and Waratah varieties is available this year. The price for graded grain has been fixed at 3s. 4d. per bushel on trucks Sandy Creek, and farmers requiring seed of the above wheats should make early application to the Manager of the Turretfield Seed Wheat Farm, Rosedale.

Publications Received.

The Library of the Department of Agriculture acknowledges the receipt of Vol. I., No. 1, *Australian Wild Life*, the journal of the Wild Life Preservation Society of Australia, Science House, Gloucester Street, Sydney. In a foreword the editor claims that the society has been a very potent agency for good in the community and has helped in no small measure to preserve for future generations of Australians that extraordinarily valuable and unique legacy handed down to them in the form of the wild life of our bush lands. The annual subscription is 5s.

Scott's Book, the life and Mildenhall-Melbourne flight of C. W. A. Scott, told by himself. Published by Hodder and Stoughton Ltd. Price, 7s. 6d.

VETERINARY INQUIRIES.

[Replies supplied by Veterinary Officers of the Stock and Brands Department.]

"Taldra" reports pony with swollen head and discharge of pus from the nostrils.

Reply—The condition may be strangles. Keep isolated in airy quarters and put on to laxative diet (green feed—mashes). Give inhalations of steam medicated with eucalyptus or turpentine and sponge nostrils at intervals to keep free from accumulations of discharge. To hasten ripening, foment swelling under jaw or rub daily with some stimulating embrocation. When soft, lance abscess and drain of its purulent contents. Syringe abscess cavity out daily with weak antiseptic solution until all discharge ceases. During convalescence give 1 tablespoonful of Fowler's solution of arsenic night and morning for 10 days on top of damped feed.

Secretary Hope Forest Agricultural Bureau reports—(1) *Itch on mane and legs of horses;* (2) *cause of and treatment for cowpox;* (3) *horse with injury to knee of front leg.*

Replies—(1) The trouble is a form of mange. To treat, wash the affected parts thoroughly with soap and warm water in which has been dissolved some washing soda, using an old scrubbing brush to work the solution on to the skin at the roots of the

hairs. When all scabs, scurf, &c., have been removed by this washing, dry the parts gently. Subsequently dress every other day (three or four applications) with the following:—Lysol, 2 tablespoonsful; raw linseed oil, 1 pint. Rub this dressing well into the roots of the hair. (2) Cowpox is caused by an ultravisible virus. It is readily transmitted from one animal to another and from cattle to human beings. Affected animals are better isolated from healthy ones, or if this is not possible, the handling of them should be left till the last and the attendant's hands subsequently washed in an antiseptic solution. The disease will run its course, and if the lesions are kept clean and are anointed with a little zinc oxide ointment before milking and dusted with dry boracic acid powder after milking, little else is required. It is not advisable to use the milk for human consumption until the case clears up. If it is healthy in appearance, the milk could be used, after boiling, for calves or pigs. (3) So long as there is heat

and pain in the swelling, apply frequent fomentations of hot water. Subsequently paint daily with tincture iodine or rub in for 15-20 minutes a little 1 to 8 red iodide of mercury blister. Clip hair over swelling before applying the blister and keep the animal tied up short for a few hours until the irritating effects of the blister have worn off. The following day wash off any remains of the blister, snip any unbroken blisters, and anoint the part with lard or sweet oil. Then turn animal out for a spell. If necessary, repeat the blister again a month later.

Secretary Blackheath Agricultural Bureau asks if oats pickled with bluestone would be injurious when fed to horses.

Reply—If the oats are pickled in a 1 per cent. solution of bluestone the grain could be used for horses provided that it is mixed with 2 parts of unpickled oats.

SORGHUM POISONING.

[By C. McKenna, B.V.S., M.R.C.V.S.]

During the past few weeks reports have been received by the Stock and Brands Department of losses amongst dairy cattle grazing on Sorghum. The history was that the cattle had been turned on to a young "second" growth of Sorghum which had appeared after the main crop had been harvested (in one case by grasshoppers). The mortalities were heavy and one dairyman lost nine cows.

The poisoning is due to the presence of Prussic Acid in the Sorghum plant at certain stages of its growth. Prussic Acid poisoning is sudden and rapid in its action. In order to prevent such mortalities in farm stock, the following points are emphasised:

(1) Crops of the Sorghum family (Sorghum and Johnson Grass, and also Sorghum-Sudan Grass hybrids) must be regarded as poisonous to stock until they have reached the flowering stage.

(2) The poisonous properties are likely to be most marked if the plants have been stunted by dry conditions or frost, or if grown on soils rich in nitrogen.

(3) Wilting does not necessarily destroy the dangerous properties, although it often has that effect.

Sudan grass (which is one of the Sorghum family) itself is not known to be dangerous at any stage of growth. However, in practice Sudan grass seed may not be "pure." The impurities are chiefly Sorghum-Sudan grass hybrids seeds. A crop grown from such seed is dangerous, as the Sorghum-Sudan grass hybrid plant is probably more poisonous than the Sorghum.

Since the above note was written, a further mortality has been reported. In this case nine cows were grazed on a crop of Sudan grass, which had previously been attacked by grasshoppers. The owner states that symptoms developed within a few minutes after the cows commenced feeding, and seven died in a short period. It is not known whether this crop of Sudan grass was produced from pure seed, but it is suggested that the same precautions should be taken in feeding Sudan grass to stock as have been recommended for the prevention of Sorghum poisoning.

As regards medical treatment of Sorghum poisoning, this is usually ineffective, owing to the rapid action of the poison. The following treatment could, however, be tried in the case of a cow:—

(1) Give the following drench immediately:—Oil of turpentine, 2ozs.; aromatic spirits of ammonia, 2 ozs.; raw linseed oil, 1 pint. (If the aromatic spirits of ammonia is not available, give in place of it 1oz. of household cloudy ammonia.)

(2) Subsequently give every hour as a drench:—1oz. of aromatic spirits of ammonia (or ½oz. of household ammonia in 2 pints of water).

The above treatment is also useful where "bloating" occurs as a complication.

SOME PARTING REFLEXIONS ON WHEAT GROWING IN SOUTH AUSTRALIA.

[Paper read by ARTHUR J. PERKINS (Director of Agriculture) at the 45th Congress of the Agricultural Bureau.]

I. INTRODUCTORY.

It must have come as a shock to most of us to find that the future of Wheat in South Australia, upon which the community had learnt to lean from its earliest days, should be questioned not only by farmers, exasperated by the cumulative losses of four successive seasons, by rival producing countries, by markets that we had come to look upon as our own, but even by sober-minded, and ostensibly impartial economists. In the latter connection I shall draw attention to an interesting article from the pen of Professor W. Henkelmann, which appeared recently in the International Review of Agriculture; it was entitled "Population Development, Wheat Production and Wheat Trade of the World."

The writer of this article argued that the great expansion of Wheat production in the nineteenth century and subsequent years was in the main attributable to the unparalleled expansion of World Population during the same period. In 1800 World Population was not quite 600 millions; in 1870 it had risen to 1,400 millions, and in 1930 to over 2,000 millions. During the past 100 years World population had doubled and relatively to 1800 it had more than trebled. This unusual increase in population led to the belief towards the middle of last century that the World was heading for extinction by famine. Malthus gave voice to the popular conception on the subject by asserting that whilst population increased in geometric progression, the production of foodstuffs increased in arithmetic progression only, and that the ultimate goal would be World famine, unless the practice of birth control became a matter of common acceptance. Hence, there is little doubt that this rapid increase of mouths to feed rendered possible, and for the time being perhaps necessary, corresponding development of unexploited colonial lands, and among the latter, of Australia; these virgin soils were required to provide adequate food for the teeming millions of the many countries that were rapidly becoming industrialised.

It would appear, however, according to the writer of the article we are considering, that the period of population expansion was rapidly drawing to a close, and that unless producing areas should be correspondingly reduced we would have to face a prolonged period of glut in foodstuffs, and unremunerative World prices for the same. At the same time Henkelmann admitted that for the present World Population continued to expand, but claimed that owing to reduction of deaths as well as births, the age character of World population was changing, and that it would not be long before the general decline in births would bring us face to face with a net population decline.

I have quoted these views because they are of general interest and because the writer of the article appeared to be biassed against the technical development of colonial expansion and committed himself to the following unacceptable view:—"The large Australian stocks (of wheat) still overshadow the World Market and prevent any improvement of the Wheat Market situation in the near future. Australia will be forced by prevailing conditions once more to restrict areas under Wheat cultivation." How the blame for low prices can justly be placed upon Australia

passes my comprehension; on the writer's own showing Australia's accumulated stock on August 1st, 1932, aggregated less than 40 million bushels, whereas on the same date total World Stocks amounted to 969 million bushels, of which U.S.A. held over 338 million Bushels and the Argentine nearly 60 million Bushels. Why, then, blame Australia for holding not much more than 4 per cent. of the Wheat available in the World on the 1st of August, 1932? As to the suggestion that Australia should reduce its wheat areas, I propose dealing with it later on.

II. THE IMPORTANCE OF WHEAT TO SOUTH AUSTRALIA.

Before attacking the problems of the future and suggestions to reduce areas under crop, I want you to consider briefly what Wheat has meant to South Australia since its inception. It can, I think, be said without any exaggeration that had not Wheat adapted itself to our special climatic, soil, and economic conditions, South Australia, at all events, and perhaps much of the rest of the Commonwealth as well, would still be in partially developed condition only, with a relatively unimportant scattered pastoral population; and although it may seem anomalous, it seems probable that in the absence of Wheat our Flocks and Herds would have been no greater, if indeed as great, than is the case at the present time, when so large a proportion of our land is directly or indirectly connected with Wheat. The fact that two-thirds of South Australia's arable land—10 million acres —was originally under Mallee Scrub confirms this view. Normally, Mallee Land carries no feed except from occasional areas of bare open plain land, and none of the land under scrub could have been economically converted into pastures except by submitting it to prior Wheat cultivation. It is impossible to imagine any other crop that could have taken the place of Wheat in the progressive development of South Australia.

Our records do not go sufficiently far back to permit of statistical measurement of the benefits of Wheat to the State since its inception in 1836. We have, however, complete records back to 1865, *i.e.*, a period of 72 years. These data show that during these 72 years we produced 1,109,775,256 bushels of wheat, representing at the average price of 4s. 7¾d. an aggregate value of £257,791,544. At the same time the values of our exported Breadstuffs over the same period aggregated £195,720,426, which sum was used towards meeting the costs of overseas purchases and the payment of interest on money borrowed to hasten the State's development.

It can be added that Wheat has also supplied our people with a cheap foodstuff, assisted in the development of Live Stock Industries, and supplied a section of the population with one of the healthiest occupations on Earth.

In Table I. at the back of this statement I have summarised in quinquennial periods the main results of these seventy-two years of Wheat-growing.

III. UNREMUNERATIVE RANGE OF 1930-1934 WHEAT PRICES.
